GULSTONIAN LECTURES,

*Delivered at the College of Physicians,
February, 1843.*

BY GEORGE BUDD, M.D. F.R.S.

Professor of Medicine in King's College, London.

—
LECTURE I.

THE subject I have chosen for the lectures which the College has done me the honour to require of me, is suppurative inflammation and abscess of the liver.

From the earliest ages of medicine, the diseases of the liver have attracted much attention, and occupied a large space in medical literature. Before the functions of the liver were clearly made out, or its intimate structure known, anatomists saw, in the large size of this organ, in its existence in animals differing widely in organization and habits, and in the obvious relation of its secretion to the process of digestion, sufficient evidence of its vast importance in the living economy, and of the serious consequences that must result from derangement of its functions.

This evidence has been greatly enhanced and extended by the more explicit results of modern inquiry. Guided by the truth, of comparatively recent discovery, that a gland may be regarded as essentially consisting of a net-work of capillaries investing a secretory duct, anatomists have discovered a liver in the form of coecal tubes, opening into the intestinal canal, in the very lowest animals, and have thus furnished the highest testimony that can be given to the importance of an organ: namely, its all but universal presence throughout the animal kingdom.

Chemists, on the other hand, in showing the fundamental relation of bile to the process of respiration, have done much to explain why the liver should be so essential a part of the animal economy, and have

proved the great consequence of a more or less complete discharge of its functions to the maintenance of life.

But notwithstanding these motives for attaching new interest to the subject, while the press has been teeming with treatises on the diseases of the chest, of the kidney, and of the stomach, comparatively few have appeared, of late years, on diseases of the liver. This, assuredly, is not owing to any falling off in our sense of their importance, but to the unsatisfactory state of our knowledge respecting them. The precision lately given to our knowledge in other departments of pathology by the introduction of new methods of research, has created a demand for information more definite and exact than pathologists have been able to supply on diseases of the liver.

The unsatisfactory state of our knowledge of these diseases will scarcely be wondered at if we reflect that many causes have conspired to render the study of them peculiarly difficult.

The first, perhaps, in importance is, that the colour and texture of the liver are such as to make it difficult, with the imperfect means of research hitherto employed, to detect in the dead body the various effects of disease, unless where this has gone on to disorganization, or complete change of structure.

In an organ whose texture is spongy, as the lung, disease produces such striking changes that we can at once distinguish their different forms, and thus learn to associate them with the symptoms observed during life; but in organs naturally solid, and also nearly of the colour of the blood, as the liver and the kidney, these changes, and especially the traces of the various kinds of congestion and inflammation, are far less obvious, and to detect and discriminate them requires a knowledge of intimate structure which has only lately been obtained, and even with that knowledge a very close and minute inspection.

In the case of the kidney, the impediment which these conditions offer to the morbid anatomist is well illustrated by the fact, that a disease so common and so fatal as granular degeneration of this organ, and signalized during life by symptoms so striking as general dropsy and albuminous urine, has been left to immortalize, by its discovery, the name of a living physician; and that even now, notwithstanding the interest it has excited for fifteen years, and the attention given to it by the best anatomists of this and other countries, the real nature of the morbid change in which it essentially consists, is, perhaps, still undetermined.

Another circumstance unfavourable to the study of diseases of the liver is, that we can obtain but little direct evidence of its physical condition during life.

When the *lungs* are the seat of disease, we may ascertain, by the evidence of our senses, if any portion of them near the surface contain the natural quantity of air, or if this, in whole or in part, be displaced by some denser matter; if the surface of the pleura be roughened by fibrine, or its sac distended by fluid; if the bronchial tubes be free, or more or less choked by secretions.

If the *heart* be the organ affected, we may not only trace its outline and estimate the strength of its ventricles, but, by the sense of hearing, penetrate its interior, and ascertain the condition of its valves. Its whole physical structure is, as it were, laid open to us.

We may, indeed, examine the liver by *touch* and by *percussion*, but we cannot by these means penetrate its surface, and discover changes in its texture and consistence. They only enable us, in some cases, to trace its outline, and form a tolerable estimate of its bulk. This, indeed, is valuable information, and more than we can obtain by similar means with respect to the kidneys. But in investigating the diseases of the latter, we have the more than counterbalancing advantage, that, day by day, we can measure the quantity, and ascertain the composition, of the urine secreted: that is, we can tell precisely the manner in which their functions are performed.

The secretions of the liver, on the contrary, cannot be collected and analysed during the life-time of the patient; indeed, until lately, they could scarcely be analysed at all, as the chemists of greatest repute were not even agreed as to what are the normal constituents of bile.

For the diagnosis of diseases of the liver, practitioners had, thus, little more to guide them than the signs of functional disturbance;—signs in all cases of doubtful import, here, if we except that of jaundice, than commonly obscure and insignificant. We cannot, then, feel surprised that the diagnosis of those diseases should be

more imperfect—our diagnosis of them less sure, and our treatment consequently more tentative and empirical—than of the diseases of any other organ of equal importance.

That such is the case is frankly confessed even by those who have made them the especial object of their study. Annesley, in his splendid work on the Diseases of India, published, as he tells us, after twenty-five years' practice, in which he had the most favourable opportunities of acquiring experience in almost every part of India; and after having, during all this time, taken notes of the symptoms, progress, and treatment of the diseases which came under his notice, when speaking of acute inflammation of the liver, one of the most frequent of those diseases, says:—"It would obviously be a great attainment on the part of the practitioner, particularly in intertropical practice, to be able to ascertain the commencement of inflammatory action in the liver, and the precise part in which it is seated. The former is, on many occasions, a point of great difficulty; the latter frequently, if not generally, one of absolute impossibility. Indeed, it is not until after many years of varied and extensive experience of this disease, that the practitioner becomes enabled to decide, with any degree approaching certainty, respecting even the organ which is disordered in the earliest stages of the complaint; and even after all his observation and boasted tact, whether mental or manual, in the discovery of hepatic derangement, he will be obliged to confess the difficulty of the subject, and see cause for still further perseverance in the career of close observation which he has been pursuing."

Very recently two of the impediments to the study of diseases of the liver have been in some degree removed. By the researches of the chemists we have obtained more precise knowledge of the composition and uses of the bile; and by the labours of Kiernan and Bowman in this country, and of Müller and Henle in Germany, we have become acquainted with the intimate structure of the organ; so that now by our unaided sight, or by help of the microscope, we can distinguish the various changes of its texture produced by disease.

Hitherto, medicine, in this department, has waited on anatomy and physiology; but now that these have done their part—now that anatomy has laid open to us the structure of the liver, and physiological chemistry has pointed out the origin, composition, and uses of the bile—it is time that medicine should do hers, and give us more precise histories than we yet possess of the various diseases and derangements to which the organ or its function are subject.

As, in speaking of suppurative inflammation

tion and abscess of the liver, I shall continually have to refer to some points of its anatomy only lately made out, I will commence with a short account of the structure of the organ.

Perhaps the best way of getting an idea of the structure of the liver, is to examine under the microscope—

1. A well-selected specimen, in which the portal and hepatic veins are thoroughly injected;

2. A recent specimen, in which the blood-vessels are empty, as in an animal killed by bleeding.

From the first specimen we may learn the distribution of the portal and hepatic veins, and the intermediate capillaries. Under one of the microscopes on the table is a thin slice of the liver of a rat, which I have selected from the numerous specimens of injected liver made by Mr. Bowman. The

FIG. 1.

P P P, twigs of the portal vein; h, a twig of the hepatic vein.

diagram now exhibited has been made from that specimen, and represents a section, in one plane, of a small branch of the hepatic vein, two or three small branches of the portal vein, and the intermediate capillaries. You see that the capillaries have nearly the same relation to the branches of the portal vein as they have to those of the hepatic. It is difficult from this section to tell which branch is portal, which hepatic.

From the trunks, both of the portal vein and of the hepatic vein, not only are large branches given off, which divide and subdivide into smaller ones, like the branches of a tree, but each branch is, as it were, hairy with capillaries, or small vessels that break up into capillaries, springing immediately from it, and forming a close and continuous network. If now you conceive similar sections to that exhibited in this diagram in other planes passing through the same branches of the vena porta and of the hepatic vein, you

will perceive that the entire liver, abstracting the trunk and branches of the vena porta and of the hepatic vein, is made up of a dense plexus of capillary bloodvessels, continuous in every direction throughout the substance of the organ. These capillary vessels immediately minister to secretion. The vessels of larger size merely serve to convey the blood to, or remove it from, them. By the circumstance of the capillaries springing immediately from the trunks and branches of the portal and hepatic trees, and not from the ultimate twigs only, space is gained: that is, a larger mass of capillaries, the immediate agents of secretion, is packed in the same space.

But, although the capillaries form a continuous network throughout the substance of the liver, we must not suppose that the same blood circulates through the entire network. The blood conveyed through any branch of the portal vein to a small mass of capillaries, having performed its part in secretion, becomes drained of the constituents of the bile, and passes out of the liver through an adjacent branch of the hepatic vein. In order, therefore, that the entire mass of capillaries constituting the liver may be duly and equally supplied with fresh portal, or biliary, blood, the whole mass must be divided by the branches and twigs of the portal vein, into smaller masses, each of which receives its portal blood from the branches and twigs which go to form it. And, in the same way, in order that the blood which has done its part in secretion may be at once carried off, the mass of the liver must be partitioned in a similar way by the branches and twigs of the hepatic vein, which will be intermediate to, or, as it were, dove-tailed with, the branches and twigs of the portal vein.

In consequence of this arrangement, if we cut into a liver in which, as is usual after death, the branches and twigs of the hepatic vein, and capillaries immediately terminating in them, are full of blood, while the branches and twigs of the portal vein, and the capillaries immediately springing from them, are empty of blood, the cut surface will be mapped out into small, tolerably equal, pentangular spaces, having the outline, formed by the portal twigs, pale, and the centre, into which a twig of the hepatic vein enters, red. These pentangular masses have been termed lobules of the liver. They have been described as isolated from each other, and each invested by a layer of cellular tissue, but Mr. Bowman has shown that this is not so, but that each lobule communicates by its capillary network with those around it. I shall have to refer to this circumstance when speaking of the morbid anatomy of abscess of the liver.

The real nature of the lobules, and the manner in which they are formed, is well

shown in the diagram No. 2, for which I am indebted to the assistance of Mr. Bowman. It represents, on a highly magnified scale, three lobules of the liver. Red size has been injected into the portal vein so as to fill its branches and twigs, and the capillaries immediately springing from them, but not to reach the branches and twigs of the hepatic vein. Blue size has been injected into the hepatic vein, so as merely to fill its branches and twigs, and the capillaries in immediate contiguity with them. The result is, that the lobules have a red outline and a blue centre.

Fig. 2.

p, twig of the portal vein; *h*, twig of the hepatic vein.

You see here, that the lobules are not distinct isolated bodies, but merely spaces mapped out by the ultimate twigs of the portal vein, and the injected capillaries in immediate contiguity with them. The twigs of the vein are, as it were, hairy, with capillaries springing immediately from them on every side, and forming a close and continuous network. The lobules appear distinct, isolated, bodies, only when seen by too low a power to clearly distinguish the capillaries. If this diagram were removed to such a distance that the capillaries could not be distinguished, the lobules would appear bounded by a uniform red line, and would have the aspect of distinct bodies.

Since the capillary net-work of the liver has nearly the same relation to the branches and twigs of the hepatic vein, as to the branches and twigs of the portal vein, we might have anticipated that a similar appearance of lobules might be formed, the circumference of each being marked by twigs of the *hepatic* vein and the capillaries immediately surrounding them, and the *centre* by a twig of the *portal* vein. This appearance is seen in what has been called, by Mr. Kiernan, the second stage of hepatic venous congestion.

When the portal vessels are empty, and only the hepatic veins, and the capillaries in

immediate contiguity with them, are filled with blood, there is an appearance of lobules, having a pale outline, formed by the ultimate twigs of the portal vein. The centres of the lobules appear as small, isolated, red spots.

If the injection extend from the twigs of the hepatic vein into the capillaries, but be not continued quite far enough to reach the twigs of the portal vein, all the capillaries of the liver will be injected, except those immediately springing from the portal twigs, and a section of the liver will present small, isolated, pale spots, where the uninjected twigs of the porta are divided. These spots being surrounded by a red band continuous throughout the liver, gives rise to an appearance of lobules just like those formed by injecting the twigs and capillaries of the vena porta, so as not to fill those of the hepatic vein.

I have said that the capillaries have the same relation to the branches and twigs of the hepatic vein as to those of the portal vein. This statement, however, requires some qualification. The branches of the portal vein are each accompanied to their smallest twigs by a branch of the hepatic artery, and one of the hepatic duct. These vessels, which are very much smaller than the corresponding portal vein, run up (as you see in this diagram copied from one of the plates appended to Mr. Kiernan's paper on the liver)

Fig. 3.

p represents a longitudinal section of one of the portal veins; *h*, *g*, the accompanying branches of the hepatic artery and duct.

on one side of it, and of course, on that side the capillaries cannot spring immediately from the venous trunk; in other words, the lobules are not in immediate contact with the vein. The capillaries terminate in twigs, which go to the vein through the space which the presence of the artery and duct

necessarily interposes between the lobules and the vein.

This artery and duct are also liable to changes in volume, and, to allow of this, some cellular tissue is placed in the portal canals, surrounding the artery and duct, and continued in a thin layer round the branches of the portal vein itself. This layer separates by a small space the lobules from the branches of the porta, and is the reason of what you may notice in the first diagram, that the outline of the branches of the portal vein is somewhat more defined than that of the hepatic vein.

The hepatic veins are not accompanied by any other vessels, and are not surrounded by cellular tissue, and, in consequence, the capillaries can spring immediately from them on every side; they are every where in immediate contact with lobules.

To complete our conception of the vascular element of the liver, we must consider the hepatic artery. We have already seen that a branch of this artery accompanies each branch of the portal vein and hepatic duct.

It has been shown by Mr. Kiernan that the hepatic artery is distributed to, and nourishes, the ligaments of the liver, its capsule, and the coats of the portal and hepatic veins and of the gall-bladder and ducts; and that the blood conveyed to all these parts by the artery passes into veins which terminate in branches of the portal vein, and ministers to secretion, like blood returned from the other abdominal viscera. These veins, which originate in the liver, and feed the porta with the blood brought by the hepatic artery, constitute what Mr. Kiernan has called the *hepatic* origin of the portal vein.

I shall have again to refer to the distribution of the hepatic artery, when speaking of the causes of abscess of the liver.

Having obtained a conception of the *vascular* element of the liver, we must next

consider the *secreting* element. This is perhaps best done by examining under the microscope a thin slice of the liver of an animal recently killed by bleeding.

In this specimen [exhibited on the table], the capillary vessels are empty of blood, and from the thinness and transparency of their coats, are scarcely visible; all that we see in looking through the microscope is a mass of nucleated cells, of a flattened spheroidal form, of a light brown colour, and almost transparent.

Fig. 4.

These nucleated cells are of different sizes, some much smaller than the rest, as if more recently formed, and not yet fully developed.

If while you are looking at this mass of nucleated cells, the capillaries, which can now be scarcely distinguished, could be filled with blood or coloured size, and rendered conspicuous, it would be seen that the whole secreting portion of the liver is a solid plexus of capillary blood-vessels, the meshes of which are filled with nucleated cells.

The mucous membrane of the gall-bladder

Fig. 5.

Diagram of simple expanded mucous membrane.

E represents the layer of nucleated cells; the dark line, B, the basement-membrane; c, the sub-mucous cellular tissue, containing v, vessels, and n, nerves.

and ducts, like the excreting ducts of other glands—in fact, like all mucous membranes, and the skin itself—is composed, as Mr. Bowman has shown, of an extremely thin, transparent membrane, without pores or visible structure, whose external or secreting surface is coated with nucleated cells. These cells, by their opposition and union, form a kind of pavement on the transparent membrane, which serving as their basis of support, has for this reason been named by Mr. Bowman the *basement*-membrane. The blood-vessels and nerves ramify behind, or on the outer surface of the basement-membrane.

This arrangement is shown in this diagram, for which I am indebted to my friend Dr. Todd, and which is used by him in his lectures to illustrate the structure of mucous membrane. (See fig. 5.)

Although there is this general uniformity in the structure of the mucous membranes, they being all composed of a basement-membrane, *paved*, if I may so speak, with nucleated cells, yet the cells differ much in form and appearance in different situations.

In the tubule of the human kidneys, as you see in this diagram, the cells, like those of the secreting portion of the liver, are spheroidal.

Fig. 6.

Human Kidney Tubule, magnified 300 diameters.

c, the basement membrane, from which the cells have been detached; *d*, a detached cell.

On one of the villi of the small intestine of a dog, represented in this diagram, for which, as well as the last, I am indebted to my friend Dr. Todd, the cells are of a prismatic form, or, as Dr. Todd has styled them, columnar.

Fig. 7.

Villus of the ileum of a dog, with the epithelium partly detached.

a, c, c, particles remaining attached; *d, e*, detached particles.

In the gall-bladder and large ducts the nucleated cells are of this prismatic form. There can be no doubt that these cells lining the gall-ducts are continuous with the nucleated cells in the meshes of the capillary net-work of the liver, but the basement-membrane cannot be traced beyond the ducts. Mr. Bowman says, that he has sought for it in vain in the lobules. These seem to be composed entirely of a dense plexus of capillary blood-vessels, the interstices of which are filled with nucleated cells.

Now the researches of Purkinje, Henle, Bowman, and Goodsir, leave no doubt that these nucleated cells are the immediate agents of secretion; that they assimilate, or, in other words, by their vital attractions, withdraw from the blood the peculiar principles of the secretion, which they subsequently discharge through the excreting ducts.

This applies not to the liver only, for it seems established as a general law—and it is certainly one of the highest and most interesting that the study of minute structure has yet disclosed—that all true secretion, whether in animals or in plants, is effected by the agency of cells; “that, however complex the structure of the secreting organ, these nucleated cells are its really operative part.”

In the secreting glands of animals the nucleated cells withdraw from the blood and elaborate the peculiar principles of the secretions, and then, in one way or another, whether by rupture or disintegration, or some unknown mode, discharge them through the excreting ducts.

The evidence of this is, perhaps, clearer in the liver than in any other gland.

On examining the nucleated cells of the liver under a high power, we find that some

of them enclose small spheroidal globules, which are recognised by their dark outline, or high refractive power, to be globules of oil or fat.

Fig. 8.

Fig. 9.

Fig. 8. Nucleated particles from the healthy human liver. Fig. 9. The same from the liver affected with fatty degeneration. *a a*, nuclei; *b b*, nucleoli; *c c c*, fatty globules.

In ordinary livers these oil or fat globules are small and few in number; but in the fatty condition of the liver in phthisis, and in that induced by keeping animals exclusively on fatty substances, they are so large and numerous as to distend the cells to double their natural size, and consequently to cause a great increase in the volume of the liver.

From the high refracting power of oil globules, we have, then, ocular proof that fatty matters taken into the system in too great quantity pass from the blood into the nucleated cells of the liver. There can be no doubt that they pass, either bodily or more or less changed, from these cells into the excreting ducts; for it has been ascertained by Henle that the proportion of the fatty constituents of the bile varies with the number and size of the oil globules in the nucleated cells.

So that if we supply an animal with fatty matter in greater quantity than its system requires, we may see an unusual amount of oil globules in the nucleated cells of the liver; and, by chemical analysis, we may discover an unusual proportion of the fatty constituents of the bile. The proof is complete that the fatty matters pass from the blood into the nucleated cells of the liver, and thence into the excreting ducts.

Most of the peculiar principles of the bile are, like fat, composed of hydrogen and carbon, and are, no doubt, eliminated in the same way, namely, by passing from the blood into the nucleated cells, and, on the rupture or breaking down of these, becoming discharged through the excreting ducts, so as to form the matter of secretion.

Direct ocular proof has also been obtained that the colouring matters of the bile are contained in the nucleated cells. Henle, in his recent edition of Soemmering, describes the nucleated cells of the liver as appearing yellowish or yellowish-brown in direct light, and as probably containing the colouring matter of bile; and Mr. Gulliver seems to have recently found an unusual quantity of bile, or at least of its colouring matter, in the

nucleated cells of the liver in two persons who died jaundiced. The biliary matter was, he says, collected chiefly round the nuclei, but was also scattered throughout the cells. In some cells it was in such quantity as to render them nearly opaque*. We can hardly have more convincing proof that, in the liver, these cells are the real agents of secretion.

The nucleated cells in the lobules of the liver are, no doubt, continuous with those in the ducts; but at present we have no accurate account of the mode of termination of the ducts, which cannot be traced into the lobules. Mr. Kiernan has indeed given a figure of what he calls the *lobular biliary plexus*, in which the bile-duct is continued into the lobule, forming there a plexus which interlaces the plexus of capillary vessels. But he means the figure to be a diagram only: he confesses that no such view of the ducts can be obtained.

I have already alluded to the cellular tissue of the liver. This, which serves to protect the essential elements of the organ, is, in man, spread in a dense layer over its surface, forming the proper capsule of the liver, and is continued into its interior in the portal canals. It is in greatest quantity on that side of the portal vein on which the duct and artery run, but a thin layer of it completely invests the branches—at least all the considerable branches—of the vein. It cannot be traced further than the ultimate twigs of the artery and duct, and does not seem to enter the capillary net-work.

To make up the rest of the organ there remain the nerves and the deep-seated lymphatics. These accompany the arteries and ducts in the portal canals, but little is known of their distribution. They have not been traced beyond the portal canals.

A knowledge of the structure of the liver enables us to explain the various shades of

* This statement, and the quotation above, are taken from an admirable essay "On the Origin and Functions of Cells," by Dr. W. Carpenter, published in the 29th number of the British and Foreign Medical Review.

colour of which it is susceptible, and which have so taxed the descriptive powers of morbid anatomists.

The mass of the organ is, as we have seen, made up of a plexus of capillary blood-vessels, the meshes of which are filled with nucleated cells, containing the peculiar principles of the biliary secretion.

As regards the vascular element, the colour will vary from pale to a deep venous red, according to the empty or congested state of the capillaries. As regards the secreting element, it will vary from a light fawn to a deep olive, according to the quantity of fat globules, and of biliary colouring matter, which the cells contain. The actual tint of the liver is the combined effect of the tint due to the vascular and the secreting elements singly.

In effect of partial injection of the capillaries, the liver, after death, generally presents two colours—a yellowish colour, and a red—the former corresponding to the uninjected portion, the latter to the injected portion, of each lobule. This gave rise to the notion, which, until the researches of Mr. Kiernan, was universally prevalent, that there were two substances in the liver, a yellow substance and a red, which were supposed to constitute the medullary and cortical part of each lobule.

It was Mr. Kiernan who first showed conclusively, that the mottled appearance so frequently observed in the liver is owing to part only of its blood-vessels being full of blood; and that, in the great majority of cases in which it presents this appearance, the hepatic veins, and the capillaries that terminate in them, are the full vessels; the portal veins, and the capillaries that spring from them, the empty ones.

The fact, that the colour of the liver, when empty of blood, is uniform and yellowish, and that the red colour we often find mixed with it depends on vessels filled with blood, is not, however, a recent discovery. Although the contrary theory has been maintained by Bichat, Meckel, Andral, and, in fact, by most modern pathologists, the fact was distinctly stated, and ingeniously proved, nearly two centuries ago, by Glisson, in his celebrated work on the anatomy of the liver.

In the chapter in which he discusses the question, whether it be the office of the liver to make blood, Glisson says,—“From this it appears, likewise, that the native colour of the liver is not red, but rather a pale yellow; and when it afterwards becomes red, it is from the great quantity of blood that flows through it. In the chick, while yet in the egg, the liver is of this pale yellow colour, up to the last day of incubation, although it then begins somewhat to change. For some days, even after the chick is

hatched, there are still the remains of this colour in the liver; but every day it becomes more and more tinged with the colour of blood.”

This passage is interesting, not only in the history of opinion, but also as showing that Glisson saw how much the texture of our organs might be elucidated by a line of study which has been followed with so much success by modern anatomists—the study of their development.

I have quoted the passage, however, not on this account, but from its bearing on my present subject, and also because it would be unpardonable in me to lecture on diseases of the liver in this place, and not pay a passing tribute to the memory of Glisson.

What may be called the chemistry of the liver—that is, the chemical constitution of the bile, the purposes it serves, the source from which it is derived—is as necessary as a knowledge of the structure of the organ, and perhaps more necessary, to enable us to explain the various derangements of its function. But it has less direct bearing on the questions that will arise in considering suppurative inflammation; and for this reason, as well as for want of time, I shall for the present pass it by.

The inflammatory diseases of the liver are usually divided into *acute* and *chronic*; but this division is essentially faulty in practice, because the terms are applied, not with reference to the kind and degree of inflammation, but to the severity merely of the local symptoms. Now, inflammation of the liver running rapidly into abscess, if deep-seated and of small extent, may give rise to but few and obscure local symptoms, and would consequently be styled *chronic*; while inflammation involving the surface of the liver, even of such kind as terminates in the slow effusion of coagulable lymph only, will be attended with well-marked local symptoms, with great pain and tenderness, and will be termed *acute*.

We shall never have true histories of inflammatory diseases—histories to serve as safe guides for their treatment—until we have learned to arrange them, not according to their outward characters merely, or the prominence of particular symptoms, but according to the nature of the causes by which they are produced; for it is a truth that cannot be too strongly enforced, that it is the *cause* of an inflammatory affection which mainly determines its course and character, and the influence that remedies exercise over it. Take, for example, the inflammatory affections of the knee-joint.

If inflammation of the synovial membrane of the knee-joint be excited by a penetrating wound, and the consequent admission of air, it causes speedy suppuration, and generally leads to destruction of the joint. If it be

occasioned by the presence of pus in the blood, it is attended with very little effusion and swelling; but, as in the former case, it terminates in the formation of pus; and that so rapidly, and with such slight local symptoms, that pathologists have even inferred that the pus, instead of being formed by a process of inflammation in the joint, is actually deposited there, ready made, from the blood.

If the inflammation be excited by the peculiar cause of rheumatism, it is attended with severe pain, and often with much effusion; but this effusion is never purulent, and is almost always absorbed after some days, leaving the motions of the joint free, and its structure uninjured.

If the inflammation be gouty, it is attended with still more acute pain and larger effusion. But the effusion here is different in composition from the effusion in rheumatism; and when its aqueous part is absorbed, particles of lithate of soda are often left on the synovial membrane and in the cellular tissue about the joint. These perhaps, by mechanical irritation, occasion fresh attacks of inflammation, which lead to fresh deposits of lithate of soda, and at length the joint is completely crippled.

If the inflammation be excited by the specific poison of gonorrhœa, it is attended, like the inflammation of gout, with abundant effusion, distending the synovial capsule and causing great swelling. There is seldom much pain or fever, but the disease is often very obstinate, the swelling, in spite of all our treatment, continuing for weeks or months.

Thus we may have—to take the two last examples—to treat two cases of inflamed knee. The appearance of the joint is exactly alike in the two cases, and in both there is great swelling from effusion into the synovial capsule. We give colchicum in both: in one case the inflammation rapidly subsides under the remedy, and the effused fluid is quickly absorbed; in the other the malady pursues its course as if nothing had been done. And why this difference? The parts affected are the same, and the changes, in outward appearance, exactly alike in the two cases. One might readily be mistaken for the other. The reason is simply this: the morbid changes are, in the one case, the effect of the specific principle of gout; in the other, that of the poison of gonorrhœa. I have here adduced a simple instance, but every department of pathology abounds in illustrations of the same truth, and leads to the conviction, that our judgment of an inflammatory affection can never be unerring, nor our treatment of it sure, unless we have ascertained the cause by which it was produced. It is, in great measure, our igno-

rance of the causes of diseases that renders the practice of medicine so uncertain.

At present, it would be premature to attempt to arrange the inflammatory diseases of the liver with reference solely to their causes; but, as the nature of the cause chiefly determines the character of the inflammation and its mode of termination, we obtain some approximation to such an arrangement by classifying them according to their effects.

I would therefore propose to arrange inflammatory diseases of the liver under the following heads:—

1. *Suppurative* inflammation, or that which leads to suppuration and abscess;
2. *Adhesive* inflammation, or inflammation which terminates in the effusion of coagulable lymph;
3. Inflammation of the gall-bladder and ducts; And to consider, as far as the present state of our knowledge permits, the various causes that produce these different forms of inflammation, and the modification of each form according to the particular cause that excites it.

I shall devote the next lecture to a consideration of the causes that give rise to inflammation of the liver that terminates in suppuration and abscess.

PRACTICAL OBSERVATIONS, WITH ILLUSTRATIVE CASES, ON THE
THERAPEUTIC PROPERTIES OF
SEVERAL MEDICINES.

By DR. HUNTER LANE, F.L.S. F.S.S.A.

Corresponding Member of the Calcutta Medical and Physical Society, Physician to the Lancaster Infirmary, &c. &c.

(For the London Medical Gazette.)

THE leaves of a tree called *mattica*, *matico*, or *matêco*, growing wild in the interior of Peru, and described by Dr. Martius, in the Pharm. Central. Blatt. Jan. 1843, as a "*Phlomis*," but delineated in the "*Flora Peruviana*" as a *Piper angustifolium*, have long enjoyed considerable celebrity among the Indians for their styptic properties when applied to bleeding surfaces, as also for their aphrodisiac virtues when internally administered. In this country they have been applied externally by Dr. Munro*, and their styptic powers fully established; but I am not aware of their medicinal action, when inter-

* Provincial Medical Journal, June 18, 1843.

nally administered, having been ascertained; wherefore it has been my desire to give the plant that honest and impartial trial which its Peruvian reputation would invite and justify.

The leaves, the parts employed, are acuminate lanceolate, slightly crenate, deeply wrinkled, of a dark green colour on the upper, and a pale green on the lower surface. They vary from three to six inches long, and from a half to an inch or more wide. They are imported in packets of a somewhat spherical shape, having apparently been strongly compressed while moist, and subsequently highly dried, but evidently not roasted, as directed by the Peruvians for external use.

From these leaves I have had two preparations made; an infusion thus—

R *Matticonis Foliorum* unciam; *Aquæ Destillatæ ferventis* octarium. *Maceræ per horas duas in vasi leviter clauso et cola;*

and a tincture prepared thus—

R *Matticonis Foliorum* uncias duas cum semisse *Spiritus Tenuioris* octarium. *Maceræ per dies quatuordecim et cola.*

These preparations have a pale green colour, faint aromatic odour, with a slightly astringent taste. They yield to the proto-chloride of tin, and subsequent treating with hydrosulphuric acid, a considerable quantity of tannin, and a substance not soluble in æther (*matticine*.*). The dose of the infusion averages half an ounce to two ounces; as an injection it may be used *ad libitum*; of the tincture, one to three drachms as a dose.

Considering the astringent and slightly stimulant properties of these leaves might prove useful in diseases originating in or depending on a diminished tone of the superficial capillary vessels of the part involved in the malady, I have prescribed it in some forms of chronic diarrhœa, but with such variable and uncertain results as not to create very sanguine expectations from its use in such cases. In Case 1 it was undoubtedly eminently efficacious, whereas in Case 3 it proved inert; and in Case 4, though a slight amelioration of the symptoms, and diminution of the ailment, took place during its use, still there was not

that benefit derived which would authorize us in supposing the *mattico* to be very effective in such diseases.

In leucorrhœa it has appeared to me to realize all the objects which Dr. Jewel would derive from the topical employment of the nitrate of silver injections, but with three superior advantages over that agent. It is more expeditious in the manifestation of its action, less variable in its operation, and more cleanly in its use. It is, however, of the last importance that proper attention be paid to its due administration, both with regard to the cases in which it is used, and the mode of its employment. In the acute form of leucorrhœa, for example, when the state of the mucous tissue affected is that of excitement approximating inflammation, where astringent and stimulant injections are contra-indicated, I should never propose the employment of the *mattico*. Indeed, it is, in my opinion, the injudicious use of such injections as those in cases of that description, which has produced those serious consequences described by Dr. Jewel and others as occasionally following their application, and which have excited in the minds of some practitioners unreasonable apprehensions regarding the employment of vaginal injections. In the chronic form of leucorrhœa, depending on a diminished tone and necessary congestion of the secernent capillaries of the mucous lining of the respective parts of the sexual apparatus whence the discharge proceeds, stimulating and astringent injections are generally found useful and effective. It is to cases of this description of leucorrhœa, whether uterine or vaginal, that I have limited my recommendation of the *mattico*; and by so doing, although it has been administered under many different circumstances, to individuals of very opposite temperaments, and of various diatheses, I have never witnessed any untoward symptom arise as a consequence of its employment. Cases 6, 7, and 8, shew the necessity of attending to the mode of its administration, and have led me, in hospital practice, to require its injection by the matron with an enema syringe. I have found it equally efficacious in menorrhagia as in leucorrhœa. Cases 11 and 12 will sufficiently exemplify its operation in

* Its chemical constitution I have not yet precisely ascertained.

this disease. Case 13 is an interesting illustration of its action in that description of varicose and ulcerated condition of the rectum, for which Dr. Houston * has proposed the topical application of nitric acid, of specific gravity 1500. In the case, however, of a child four years old, having prolapsus ani, with hæmorrhage at each defecation, its injection into the rectum, and application as a lavement to the protruded gut, was unattended by any benefit. In the case of gleet, it has, as Cases 14 and 15 shew, proved hitherto abortive; though, if I were confident of its proper employment, I should expect different results; at least its efficacy in such instances may be regarded as problematical.

Amongst the many diseases in which it seems to me that this remedy is worthy of judicious trial, may be enumerated hæmatemesis, hæmoptysis, dysentery, and certain kinds of hæmaturia. I have already, as Case 16 proves, unsuccessfully prescribed it in those sweatings which often, amongst factory people especially, precede and accelerate the sudden and rapid development of pulmonary phthisis.

Notwithstanding the high reputation which these leaves have acquired for their aphrodisiac properties, I have not, in the many instances in which I have now used it, observed the least manifestation of any such influence, nor of any emmenagogue operation.

CASE I.—Ellen Hayhurst, 21 years old, of a sanguineo-choleric temperament, sickly look, and scrofulous diathesis, with strumous enlargements of the parotid glands, came under my treatment at the hospital on the 1st April, 1843, for diarrhœa, from which she had suffered for the last six months.

With as generous a diet as she could afford, abstaining from tea, coffee, and recent vegetables, she was directed to take two table-spoonfuls of the following mixture thrice a day:—

R Decoct. Aloes Comp. ζ iv.; Infusi Matticonis, ζ v.; Træ. Matticonis, ζ j.; Træ. Iodinii, ζ ss. M. ut fiant mistura.

April 15th.—The bowel complaint gradually began to subside soon after taking the medicine, and entirely ceased about the fourth day. Her

bowels are perfectly natural, and she has had no recurrence of the disease.

CASE II.—Mary Harrison, æt. 37, of a very delicate haggard look, anæmiated aspect, and debilitated constitution, became my patient at the hospital on the 3d of April, 1843, in consequence of the effects of unduly prolonged lactation, of which diarrhœa and leucorrhœa were the most conspicuous symptoms. The child, which was nearly two years old, was ordered to be weaned, and stimulant chalybeate medicines prescribed. With these she persevered for nearly three weeks, with benefit to her general health, amelioration of the bowels, but no diminution of the vaginal discharge. She was then directed to have, in addition to her medicines, the following:

Infusi Matticonis uncie quatuor per vaginam nocte maneque injiciendæ.

This treatment she continued for a week, when she ceased to have any discharge.

CASE III.—Mary Sowerbutts, a tall athletic woman, 26 years of age, of a choleric temperament, debilitated by a long-continued diarrhœa, became my patient at the infirmary on the 26th May last. She had for twelve months past been subject to a relax, which affected her two or three times every morning, and at least once in an evening. A profuse leucorrhœa was also added to her other ailments.

Recommended, along with farinaceous food and good broths, instead of tea or coffee, an abstinence from malt liquors, and the use of one or two glasses of wine a day, to adopt the following medical treatment:—

R Infusi Matticonis, ζ vij.; Træ. Matticonis, ζ j.; Confectionis Aromaticæ, ζ ij.; Acidi Hydrocyanici Diluti, \mathfrak{m} xl. M. capt. coch. ij. majora iterum tertioque de die.

Infusi Matticonis ζ iv. uterum omni mane injiciendæ.

On the 8th June the uterine discharge had totally disappeared, so that the injection was discontinued. The bowels, however, were no better.

June 15th.—There has been no return of the leucorrhœa. The diarrhœa, notwithstanding sixteen days' steady employment of the mixture, remained unmitigated, wherefore the mattico was displaced by other medicines.

* Dublin Medical Journal, March 1843.

CASE IV.—T. H., Esq. a surgeon practising in Westmoreland, about 43 years of age; small, compact, athletic figure, healthy appearance, sanguineo-choleric temperament and active habits, consulted me on the 29th of December, 1842. For several years he had been afflicted with a chronic matutinal diarrhœa. The first thing every morning he had been obliged to go to stool, and the same call was repeated generally thrice in succession. During the remainder of the day he was free from such intestinal annoyance; and was in other respects perfectly well.

His teasing, but otherwise apparently unimportant complaint, had resisted the influence of opiates, alteratives, purgatives, and tonics. To a long-continued indulgence in bitters he had, indeed, attributed the state of his bowels.

A generous animal regimen, the substitution of a moderate quantity of brandy and water or port wine for malt liquors, and the subjoined medicines, constituted the course prescribed.

R Infusi Matticonis, ℥vij; Træ. Matticonis, ℥j.; Pulveris Rhei Usti, ℥ss.; Sodæ Sesquicarbonatis, ℥iiss.; Confect. Aromaticæ, ℥ij. M. capiat coch. ij. majora quartâ quâque horâ.

R Fellis Bovis Inspissati, ℥ss.; Pilulæ Hydrargyri, gr. xii.; Olei Carui. ℥v.; M. ut fiant massa in pilulas xii. distribuenda equibus; cum singulis dos. misturæ devoranda.

For three months he said that the course of treatment had been observed; but there was not that amount of improvement which such perseverance in its use would justify us in expecting. The monesia was therefore substituted, and with excellent effect.

CASE V.—Jane Marshall, æt. 31, a tall, well formed, but unhealthy looking unmarried woman, of a choleric temperament, and remarkably hysterical disposition, labouring under amenorrhœa, came under my care on the 17th of April, 1843. She complained of great pain in the head, had ptosis of the left eye, and the tongue when protruded was slightly turned to the left side. Her appetite was bad, her bowels confined, and for the last week she had had morning sickness. She had not menstruated for three months; but this catamenial irregularity was a common

occurrence with her, as also leucorrhœa, under which she was then suffering.

A plain nutritious regimen, regular exercise in the open air, and the following medicines, were prescribed:—

R Infusi Valerianæ, ℥viiss.; Træ. Valerianæ Amm. ℥ss.; Acidi. Hydrocyanici Dil. ℥xl. M. capiat coch. ij. majora ternis horis in die.

R Pilulæ Hydrargyri; Extracti Colocynth. Comp., Extracti Hyoseyami, aa. ℥ss.; Antimonii Potass. Tartr. gr. iss. M. ut fiant massa in pilulas xxiv. dividenda quarum, ij. omni nocte sumantur. Vescitorium nucis admodum Infusi Matticonis uncis quatuor vaginam omni mane injiciendæ.

On the 27th April, she stated that after using the injection four or five days "the whites" entirely disappeared. She felt relieved also in her head, and much improved in general health. By subsequently continuing the anti-hysterical treatment, she escaped from her threatened paralytic affection.

CASE VI.—Anne S—, a married woman, 26 years old, of a weakly form and attenuated appearance, melancholic temperament, and phthisical diathesis, was admitted under my care on the 1st of May, 1843. She supposed that her husband had communicated the syphilitic disease to her. Upon examination, however, she was found to be suffering from considerable leucorrhœa, and to have a simple bubo in each groin. For some time she had had indigestion, with constipated bowels, and indications of incipient prolapse of the womb.

The buboes were ordered to be fomented two or three times a day with hot water, rest was strictly enjoined, and the following treatment, with liberal diet, prescribed.

R Magnesie Sulphatis, ℥ss.; Infusi Gentianæ Comp. ℥vij.; Træ. Gentianæ Comp. ℥j.; Acidi. Sulphur. Dil. ℥j.; Ferri Sulphatis, gr. viij. M. capiat coch. ij. majora ter indies. Infusi Matticonis uncis quatuor nocte manequè in vaginam injiciantur.

On the 8th of May she reported herself as better; her bowels were regular, but somewhat griped; the bubo in the left groin was suppurating, and the leucorrhœa had entirely ceased soon after using the injection.

She was directed to discontinue the injections, and ordered some chalybeate tonic and aperient medicines.

18th. — Very much improved in general health, but the vaginal discharge had returned.

She continued the use of the injections for a fortnight without any abatement of the discharge. The matron directed to administer the injection with an enema syringe, so as thoroughly to wash the cavity of the uterus; after which she had no longer any discharge.

CASE VII.—Agnes Varley, æt. 18, of a delicate form, sickly look, and anæmiated complexion, came under my care on the 15th of May, 1843. She is of a sanguine temperament, exceedingly scrofulous diathesis, has enlarged glands on each side of the neck, and is distorted by a postero-lateral curvature of the spine; added to which she had a profuse leucorrhœa.

For two months she had been treated by iodine and iron, combined with generous regimen, with decided benefit to her constitutional health, but no amelioration of the vaginal excretion, wherefore she was directed to use three or four ounces of the infusion of mattico as an injection *per vaginam* night and morning. This course she pursued for a month without any obvious advantage; the matron was therefore directed to administer the injection so as effectually to wash out the vagina.

A week afterwards she stated that since the matron administered the injection she has had no discharge. At present she is under my care for her constitutional maladies, and says she has had no re-appearance of the leucorrhœa.

CASE VIII.—Agnes Howson, æt. 32, a delicately formed sickly looking woman, of a leucophlegmatic habit and scrofulous constitution, came under my care on the 29th of June, 1843. She presented all the corporeal evidences of impoverished diet, and long protracted lactation, of which leucorrhœa was one of the most distressing concomitants. The discharge she stated came from her in gushes while in bed, and the least exertion wrung it from her at any time.

A puny, unhealthy looking infant, of 22 months old, which she was suckling, was directed to be immediately weaned, and the patient to live well, being allowed a pint of ale or porter daily, to have the womb injected with the infusion of mattico, and to take the following mixture.

℞ Decocti Aloes Comp. Infusi Gentian.
Comp. aa. ʒiiss.; Træ. Gentianæ

Comp. ʒv.; Træ. Cantharidis, Træ. Secalis Cornuti, aa. ʒiss.; Ammonio Tart. Ferri ʒj. M. ut ft. mistura, de qua capiat coch. ij. majora ter die.

July 20th.—After the injection the leucorrhœa gradually subsided, so that on the second day it entirely ceased, and has not since reappeared.

CASE IX.—Sarah G—, an obese, strong looking woman, 58 years old, florid complexion, sanguineo-choleric temperament, applied to me at the hospital on the 13th of July, 1843, in consequence of her suspecting that her husband had given her gonorrhœa. For the last week she had had such a profuse discharge, that neither repeated washings, nor the constant application of cloths, could keep her clean. The labia and upper parts of the thighs were excoriated and inflamed, and she had scalding in making water; all which on inspection proved to be the effects of leucorrhœa.

To take no medicine, but to have the womb well injected by the matron with half a pint of the infusion of Mattico.

On the 5th of August, she stated that the single injection had completely cured her; and she has been quite comfortable, and free from discharge, ever since its administration.

CASE X.—Elizabeth Bainbridge, æt. 28, a mother of three children, the youngest two years old, came under my care at the hospital on the 15th July, 1843, for chronic bronchitis; suffering at the same time from considerable uterine irritation and abundant leucorrhœa.

In addition to the treatment of the malady for which she applied, she was directed to inject four ounces of the infusion of mattico every morning into the uterus.

For a fortnight she observed the directions given, but found no amelioration of the discharge. The bronchitic symptoms having subsided, ferruginous tonics were prescribed, and the matron directed to inject the infusion of mattico into the uterus.

Since the day after the administration of the injection, when she was teased with urticaria, she has had no re-appearance of discharge.

CASE XI.—Elizabeth Poppin, æt. 30, of a sanguine temperament, delicate look, emaciated appearance, and presenting the symptoms of enervation, the consequence of some continued or

excessive flux, became my patient on the 29th of April, 1843, for menorrhagia. She had had five children, the youngest being two years old, and for the last nine months she has been unceasingly afflicted with the present disease.

With a recommendation to use as generous a regimen as she could afford, the following mixture was prescribed.

R Infusi Matticonis, ℥vij. ; Træ. Matticonis, ℥ss. ; Træ. Secalis Cornuti, ʒij. ; Træ. Valerianæ Amm. ʒss. M. capiat coch. ij. majora ternis horis quotidie.

May 4th.—No improvement.

Mistura eadem repetatur. Per vaginam infusi Matticonis unciae quatuor nocte maneque injiciendæ.

22d.—The discharge gradually diminished while using the injection, and for the last eleven days she has not "seen any thing." Discharged cured.

CASE XII.—Ellen Moon, æt. 30, of a light, ruddy complexion, small delicate figure, sanguine temperament, and hysterical habit, suffering from menorrhagia, came under my care on the 24th of July, 1843. Her youngest child is four months old; since its birth she has been incessantly afflicted with her present complaint, and feels her mind and body much impaired by the continued drainage.

With a good diet, including half a pint of ale or porter daily, to observe the following prescriptions.

R Quinæ Disulphatis, gr. xii. ; Ferri Sulphatis, gr. viij. ; Zinci Sulphatis, gr. iv. ; Aquæ Puræ, ʒviiss. ; Træ. Zingiberis, ʒss. ; Acidi Sulphurici Dil. ℥x. M. capiat coch. ij. majora ter de die. Uterum matronæ nosocomii infusi Matticonis unciae sex instantèr injiciendæ.

August 14th.—Discharged cured. She has had no uterine or vaginal discharge since the administration of the injection.

CASE XIII.—On the 5th of January, 1843, I visited Mrs. R——, Cheetham Hill, near Manchester. She was upwards of 50 years of age, of a sanguine temperament, strumous constitution, small, delicate, juvenile-looking form, exsanguinated appearance, with an anxious and dispirited expression of countenance, and the physiognomic signs of continued physical suffering. When *enccinte* of her second child she

took a quantity of sugar of lead in mistake for Epsom salts. The error was, however, quickly discovered, and antidotes were timeously and successfully administered. But from that period she dates the origin of her malady, which progressed with each succeeding pregnancy; so that for twenty years past she has been fruitlessly seeking benefit from our science. During the last two years she has had no evacuation of the bowels without the use of aperient medicines, and even with such aid defecation has always been attended by great tenesmus and severe bearing-down pains, "more like the cutting pangs of labour." Enduring this excruciating misery she has been compelled to remain from half to three quarters of an hour on each occasion on the *commode de nuit*. The fæces, which are generally white, and of a clayey appearance, are usually besmeared with a muco-purulent matter, but preceded by a quantity of black grumous blood, evidently the accumulation of effused blood in the rectum. Defecation always terminates in a prolapsed condition of the gut, so that she is necessitated to lie down until a spontaneous reduction occur, but more generally she is obliged by manual assistance to restore the parts. While sitting up, the prolapse usually recurs to such a degree that she is required to have her chair so arranged with cushions as to render the sitting posture even tolerable. The same descent of the gut attending every effort to walk has deprived her of that mode of exercise, and compelled her to take airings in a bath chair suitably constructed to accommodate the anal malady. An inspection immediately after defecation discovered the anus surrounded by a prolapsed, highly vascular, mulberry surfaced, bleeding membrane; an examination by the finger, per anum, detected an exceedingly tender, thickened lining of the rectum, with a varicose state of its vessels.

She was recommended to live almost entirely upon animal food, with bread or cabin biscuits, taking wine at luncheon, and cold gin and water at dinner and supper. The subscribed medicines were advised.

R Fellis Bovis Inspissati, ʒij. ; Creasoti, ℥vj. ; Pilule Hydrargyri, gr. xii. ; Extracti Gentianæ, ʒj. ; M. ut fiant

massa in pilulas xxxvi. dividenda, de quibus ij. nocte maneque sumende.

R Decocti Aloës Compos. ʒiiss. ; Infusi Gentianæ Comp. ʒvss. ; Træ. Gentianæ Comp. ʒj. ; Ammonio. Tartr. Ferri, ʒiss. ; M. ut fiant mistura de qua capiat coch. ij. majora ter de die.

To the first of February she scrupulously observed the injunctions enjoined, when she felt better in general health, had less bleeding, and less pain during the evacuation of the bowels. In two days afterwards, however, she had another hæmorrhagic attack, which reduced her very much; the gut descended at each effort at defecation, with increased pain, and she suffered considerable irritation of the rectum after each reduction of the membrane.

A continuance of the same medicines and regimen, augmenting the quantity of wine in proportion to the sinking of the powers, was recommended; but in addition to have four ounces of the infusion of mattico injected night and morning into the rectum, and retained there as long as possible.

When I visited her on the 13th of February she was very remarkably improved. She had only found it necessary to use the injection five times, as the hæmorrhage had gradually diminished until five days ago, when it had entirely ceased. Her bowels were more naturally moved; the prolapse considerably less, and spontaneously reduced on lying down. She complained much of the pain experienced during and immediately after the use of the injection.

In usu Pilularum Misturæque perstet.

On the 26th February, she had a slight return of the hæmorrhage, which was at once arrested by a single application of the mattico infusion as an injection. She complained of an annoying irritation of the rectum, almost amounting to tenesmus, which I regarded as the effect of the aloes, but as that was originally prescribed for its specific action on the mucous lining of the rectum, I, instead of withdrawing it, preferred the recommendation of an occasional suppository composed of extract of opium and hyoseyanus, with soap.

March 2d.—Again visited Mrs. R—, whom I found perfectly convalescent. The suppositories had afforded the desired relief. Defecation, occurring

every morning and evening, was accomplished without pain or bleeding; the membrane scarcely ever escaped, and when it did so, never suffered strangulation as it receded, even while she was standing. She had quite given up the use of the bath chair, and had been walking a mile or two daily.

Up to the present period she has had no recurrence of her malady, and is now in the enjoyment of perfect health.

CASE XIV.—J. R. H—, Esq. of Smedley, near Manchester, consulted me on the 17th Aug. last for a gleet, the effect of a gonorrhœa which he had contracted a month previously. With the sulphate of magnesia and bitartrate of potassa as a laxative and diuretic, I advised the urethra to be injected morning and evening with the infusion of mattico. He assiduously, he said, but fruitlessly, followed my directions for eight days, when I substituted an injection of sulphate of zinc and sulphate of morphia, which had only need to be used thrice, when the discharge was stopped.

CASE XV.—Mr. J. B— had suffered from a gleet for three or four months. He had tried various injections, conjointly with the internal use of copaiva and cubebs, but without any benefit. He consulted me on the 1st ult. when I prescribed a brisk turpentine purge, and the injection of the urethra every night with the infusion of mattico. At the end of a week there was no improvement. The injections were discontinued, and the following mixture prescribed.

R Decoct. Scoparii Comp. ʒvij. : Træ. Capsici, Cantharidis, Secalis Cornuti, aa. ʒiiss. M. capiat. coch. ij. majora tertia quæque horâ.

In four days all appearance of gleet was dispelled.

CASE XVI.—W. T—, a young man, 19 years of age, dark complexion, delicate form, unhealthy consumptive look, scrofulous diathesis, and melancholic temperament, consulted me on the 12th January last. He was suffering from those excessive sweats which often precede, usher in, and seemingly accelerate, the rapid development of pulmonary phthisis. He had no cough, though the stethoscope shewed that his lungs were studded with consolidated matter; his bowels were regular, and his appetite voracious.

Ordered to have his body sponged every morning with a cold infusion of mattico, and, with a plain good nutritious regimen, to take the subjoined mixture—

℞ Infusi Matticonis, ℥vij. ; Træ. Matticonis, ℥j. ; Quinæ Disulphatis, gr. xij. ; Acidi Sulphur. Dil. ℥j. ; M. capiat. coch. ij. ; majora iterum tertioque de die.

In this treatment he unremittingly persevered for three weeks without any benefit; therefore other medicines were substituted.

[To be continued.]

TREATMENT OF GONORRHOEA.

To the Editor of the Medical Gazette.

SIR,

A LETTER published in your journal by Mr. Childs, of London, recommending the superficial cauterization of the urethra as a cure for gonorrhœa, has induced me to give publicity to the following case.

A young gentleman, aged 26, put himself under my care for syphilis, six months ago, which, in the usual time, was cured, when he directed my attention to his urethra. He had not passed his urine for some time with ease and comfort, the stream was much smaller than usual, &c., and, in short, he had all the symptoms of stricture of the urethra. I attempted to pass a moderate-sized bougie, but failed, it would not even enter the orifice; I tried each size in succession down to the smallest but one, which passed through the stricture, and met with no obstruction in its passage to the bladder afterwards. The stricture appeared to be nearly an inch long, and the urethra seemed to the feel to be much indurated for a corresponding extent. I inquired into the cause of the disease, when he said that he had contracted clap twelve months ago in a neighbouring town, and had applied to a surgeon, who introduced a piece of nitrate of silver into the urethra for a short way, (he thinks about an inch and a half,) once or twice, and, as he stated, "burnt it out very carefully," and he got well in a very short time without any thing else being done. Now it is evident that this case proves two things: 1st, that the cauterizing plan was used before Mr. Childs adopted it; and, 2ndly, that it is not a safe remedy, but

that it is liable to produce strictures. It must be evident to all that the above case of stricture was produced by it. It soon followed it, and was *confined* to the parts subjected to the remedy; the gonorrhœa had not time enough to cause it, as it had not existed more than three or four days at most. By using bougies for a short time the stricture was cured. Mr. Childs would do some service to the profession by keeping his cases under his eye, in order to ascertain whether or not stricture ensues, and what condition seems necessary to induce it, and whether a severe application of the caustic is liable to produce it (which is most probable) or not?

If the new mode be found to cause stricture, which I am much inclined to think will be the case, it will be doomed to merited oblivion as an evil to be avoided: those are points which ought to be well ascertained before venturing further with the plan, and which I hope Mr. C. will investigate carefully, and publish the result of the research, until which time I shall not be inclined to give it a trial.—I am, sir,

Your obedient servant,

J. D. BROWN, M.R.C.S.L.

Haverfordwest, Sept. 17, 1843.

PYROLIGNEOUS ACID.

To the Editor of the Medical Gazette.

SIR,

WILL you favour me, by inserting in your number of Friday next, the following observations, which I should have sent to you a week sooner, had not the No. 51 of the LONDON MEDICAL GAZETTE, for 15th Sept. 1843, been delayed a week, in its delivery here, through the negligence of the supplying bookseller.

Dr. Willis, of Brighton, has in that No. inserted some remarks of Dr. Wigan, on the use and efficacy of Beaufoy's Pyroligneous Acid in Tinea Capitis, with a view to a more general trial of that remedy than hitherto. It will doubtless give pleasure to the benevolent originator of the practice, to find, that some of the seed he has attempted to sow has taken root. I hope it will be found that many other practitioners have profited by his instructions as well as myself.

It was not till lately (some two or three years ago), that I read a paper of printed instructions, which in 1843, Dr. Wigan was at the trouble and expense of sending to a great many of the leading medicos of that time. Since the time I have mentioned, I have tried the acid in the way recommended. I have seen its efficacy both as a detector and a curer of the disease in question, in very many cases. I have witnessed its success, also, in the practice of my friend, the highly respectable and intelligent surgeon of the Blue Coat School, in this place, which has until lately presented an extensive field for practice in this disease; indeed, where ringworm had been for many years prevalent, and had bidden defiance to all attempts at cure and eradication.

The summary of my experience is, that Dr. Wigan's remarks and instructions will in every respect be verified; and that my medical brethren, if they try this application, will have to thank Dr. Wigan for an application more efficacious than any other, or all others, hitherto tried: only, to secure a fair trial, care must be taken—1stly, to make out a clear diagnosis; 2dly, if any other disease of the scalp co-exist, to get rid of that disease first; 3dly, the medical man must himself apply the remedy, and not trust to relatives or friends; lastly, to avoid exciting the "disease of the doctor." I have seen the acid used undiluted, without any detriment. The soundness of any previously diseased spot may be tested by the hairs on and around not being plucked out *readily and without pain*.

As an individual practitioner, who has had to wrestle with this disorder, I beg, through your columns, to thank Dr. Wigan for the knowledge of a very valuable remedy in a complaint hitherto very intractable.

For directions, in detail, I must beg to refer to the excellent instructions published by Dr. Wigan.—I remain, sir,

Your obedient servant,
J. J. FURNIVALL, M.D.
Physician to the General Infirmary
at Hertford.

Hertford, Sept. 23, 1843.

RETAINED PLACENTA—FATAL HÆMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case deserving of publicity, you will oblige me by inserting it in your GAZETTE at your convenience.—I am, sir,

Your obedient servant,

J. MOYLE.

Chacewater, Sept. 27, 1843.

I was requested a few mornings since to visit Mrs. B. I accompanied the messenger, and on reaching the house found that she had, about three hours and a half before, given birth to a child, and was then moribund from severe hæmorrhage, in consequence of the gross ignorance of the midwife, who did not know how to remove the placenta, which I found in the os uteri and vagina folded, with bleeding through the canal thus formed. She told me that she had not made any attempt to remove the placenta; nor had she used any means to suppress the hæmorrhage, which was so very profuse that the bed was saturated, a good sized *pot de chambre* half full of coagula, and the floor so deluged that the midwife had a thick rush mat to stand on at the foot of the bed. I immediately gave a little cold brandy and water, grasped the fundus uteri, and after a few minutes easily removed the placenta. She died in about half an hour after my arrival. I wrote to the coroner, and expressed a hope that he would hold an inquest; but to my surprise he took no notice of the case.

Perhaps, sir, you or some of your numerous correspondents will inform me, through the medium of your journal, whether the coroner acted right in allowing this case of—shall I say manslaughter, to pass unnoticed.

USE OF SYMBOLS.

To the Editor of the Medical Gazette.

SIR,

I BEG you will allow me, through the medium of your respectable journal, to communicate to those medical students who may be commencing their logical

studies, a mode of expressing the categorical propositions by pure symbols, which will materially facilitate their labours. I have had some experience with the plan, which I put to the test a few years ago in teaching a medical pupil; he found considerable difficulty with the mixed symbols, as given in books, but readily saw the use of the pure symbols.

The plan consists in simply pointing the distributed terms. The point may be placed before or above the symbol of the term. In writing I usually place it above: thus A will

be $\dot{Z} X$ E, $\dot{Z} \dot{X}$ I, $Z X$ and O, $Z \dot{X}$

It is evident that $\dot{Z} X$ must be A, because the subject but not the predicate is distributed. The student will here see at a glance that its simple illative conversion is impossible. By the use of these symbols all the moods may be tried in the different figures in a very rapid and satisfactory manner. The following is Barbara placed in the second figure, Y being the middle term:—

$\dot{X} Y$

$\dot{Z} Y$

$\dot{Z} X$

Thus we detect immediately the common fallacy of an undistributed middle term.—I am, sir,

Your obedient servant,

JOSEPH HOULTON.

ON
SEMINAL (?) DISCHARGES FROM
THE URETHRA;
AND ON THE
INFLUENCE OF CREOSOTE
IN
MUCOUS AND SANGUINEOUS DISCHARGES.

By R. H. ALLENATT, M.D. A.M. F.S.A.

(For the Medical Gazette.)

MR. JAMES DOUGLAS, in a late number of the MEDICAL GAZETTE (Sept. 29), has detailed a case of what he conceives to be spermatorrhœa, arising from masturbation, and has suggested a remedy

which appears to have been as efficacious as Lallemand's plan of cauterizing the urethra; and it certainly possesses the advantage of being much less hazardous to the patient. There is one point, however, in the communication, upon which I feel a little doubtful, and that is respecting the loss of *semen* which is alleged to have occurred "without ejaculation, and with scarcely any erection." A case closely approximating to that of Mr. Douglas fell under my notice a short time ago, and first awakened the suspicion which subsequent facts have tended in some measure to confirm. The case is this:

A man, aged 33, unmarried, who had from puberty been addicted to a solitary vice, contracted at a large boarding-school, came to me in great alarm, stating that when at stool, frequently in making water, and sometimes too in sleep, in the absence of libidinous emotions, he lost a considerable quantity of semen. Upon inquiring into the case, I was led to question the nature of the discharge; and putting him in the way of instituting for himself a careful and minute observation, I subsequently learnt that it consisted of limpid colourless mucus, without the sensible characteristics of pure seminal fluid. The testes in this instance were healthy, not particularly pendulous, and certainly not so flaccid as they should have been had a perpetual drain of their secretion been established. This patient was placed under a course of chalybeate tonics; and without the aid of cauterization, or other local applications, he gradually recovered.

From the anatomical structure of the parts, we can fully comprehend how, by long-continued, preternatural excitation, they may ultimately lose their tone, fall into a state of debility, and the secretions from the patulous orifices of the weakened vessels may be augmented. The prostate secretes a ropy mucus: the glands of Cowper, seated anteriorly to the prostate, also secrete mucus: mucus is secreted in abundance, in certain morbid affections, by the internal coats of the bladder; and the canal of the urethra is bedewed with mucus from the glands and lacunæ scattered throughout its course. A mechanical obstruction is, moreover, I believe, offered to the flow of semen, during the passive state of the organ,

by the *sinus Pocularis*, whose mouth being directed forward, forms a valve, which is closed by the collapsed urethra: at all events it is hermetically sealed, during micturition, by the force of the stream, so that no semen can escape "during the time of making water."

Under these circumstances I rather incline to the belief that, in the majority of cases cited by recent authors, the fluid passed is not seminal but mucous; but I shall be glad to learn if there be any *test* to facilitate the discrimination.

Influence of creosote in mucous and sanguineous discharges.

I have published, from time to time, in the medical periodicals, cases which presented themselves to my notice, in which the direct application of creosote to morbidly secreting mucous tissues was followed by speedy amelioration of previously existing symptoms. The first case to which I directed the attention of the profession was that of gonorrhœa (MED. GAZ. Feb. 28, 1840), in which the discharge was subdued by this remedy in the course of a few days. The next was a case of inveterate fluor albus, the details of which appeared very lately. I have just now met incidentally with another case of gonorrhœa, in which the discharge was copious and thick, of several months' duration, and not at all inclined to degenerate into the thin gleet secretion of chronic clap. In this case (for I need not enter into detail) the discharge was arrested at once by the creosote injection, and has not since returned. I may mention, however, that in consequence of the sudden stoppage of the flux, an eruption appeared on various parts of the body, resembling syphilitic psoriasis. It speedily yielded to gentle laxatives, combined with tonics.

The next case is that of purulent otorrhœa:—William Payne, Charles Street, Westminster, one of my morning patients, came to me about a fortnight ago, on account of a discharge from the left ear. The external meatus was filled with thick pus, and the lobe of the ear, and all the parts adjacent, to which the acrimonious matter gained access, were inflamed and excoriated. I ordered an injection, composed of a drachm of creosote, the same quantity

of liquor potassæ, and six ounces of water, to be frequently thrown into the tube. The ear and excoriated surfaces were defended by a simple unguent. At the present time the discharge has completely ceased, the natural functions of the organ have been restored, and the sores are healed.

Bleeding hæmorrhoids.—It was by accident I discovered the power of creosote in restraining hæmorrhage from piles. A gentleman was under my care suffering from another disorder, for which I ordered the internal exhibition of creosote. I was not aware at the time that he suffered occasionally great losses of blood from the lower bowel. He surprised me one day by stating, that since he had taken creosote (upwards of a month) the bleeding had not occurred, which had been habitual to him every week or ten days for the last eight or ten years. To test the power of creosote, I discontinued its use for a short time, and the hæmorrhage returned, but in much smaller quantities than before. On returning to the remedy, the bleeding again stopped.

In another case of a similar description the same effects were produced.

It is time we possessed a rational exposition of the action of creosote on morbidly secreting mucous tissues, for I believe it possesses immense power both in restraining passive hæmorrhages, and in subduing inordinate secretions.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Pulmonary Consumption, successfully treated with Naphtha. By JOHN HASTINGS, M.D. Senior Physician to the Blenheim Street Free Dispensary.

A CURE for pulmonary consumption! We feared the day had gone by when such an agent was to be hoped for; but our apprehensions were premature, and the long-sought-for panacea has at length been found in naphtha.

The first portion of the volume before us is devoted to a general account of the disease in question—its causes,

symptoms, complications, pathology, &c. We then come to the treatment, on which some general remarks are made, and these being disposed of, the particular object of the volume is pointed out, namely, to introduce to the public the remedy above mentioned. The following are our author's remarks on this part of the subject:—

“Thus far regarding the treatment of pulmonary consumption there is little but what has been adopted by some one or other practitioner, although in its connected form it may have some claim to originality; but that which I have now to describe is altogether new, and forms that part of the treatment which may strictly be termed medical. The reasons which induced me to deviate from that line of medical practice, which has so universally and for so long a time been in vogue, for that which I now submit to the profession, was the fatal termination of all cases, whatever was the treatment adopted, during an experience of upwards of twenty years. I was led to the conclusion, from a careful survey of the chemical analysis of tubercle made by Thenard*, and the only analysis of this morbid product in a crude state that I am aware has been made, that it was defective; inasmuch as the composition of the animal matter, which it will be observed amounted to upwards of ninety-eight parts out of a hundred, had not been investigated. From the greasy nature of tubercle in its crude state, there did not exist the slightest doubt in my mind that carbon entered largely into its formation, and that its composition had a striking resemblance to fatty matter. This opinion has been strengthened by the discovery of those spherical globules which I have described in the chapter on the ‘Pathological condition of Pulmonary Consumption.’ Further investigation may prove that the last change effected in tubercles, before being expelled from the lungs, is a return to that normal structure from whence they derived their existence, which will not only be a curious but highly interesting fact. It may be readily conceived that the morbid action which had for its end

the formation and maintenance of tubercles in the lungs would, in a great measure, lose its influence over them when they become softened and more or less separated from the living tissues, with which they were formerly in close connection. For among the changes in the earlier stages of pulmonary consumption none is more remarkable than the disappearance of fat, and as the disease advances all the tissues of the body become more or less attenuated, the muscles of involuntary motion excepted, which it is alleged do not obey this destructive process. There is, however, a want of facts relative to this point to thoroughly decide the question. In consequence of the loss of fat, I determined to employ those compound agents rich in carbon and hydrogen, which had not been previously used in medicine; not with the idea that they would make up the deficiency which the system had sustained in the progress of the disease, but that such a change would by that means be introduced into the constitution as would act upon the forces of the organism at the point of departure from health, whether that took place in the stomach, blood, or elsewhere;—that change tending to such an affinity in the elements within the body, that the carbon, hydrogen, oxygen and nitrogen, instead of assisting in the formation of products which threaten life, would tend to develop those materials only which are required for the perpetuation of health, and the prolongation of existence.

“Naphtha, from its chemical composition and unknown properties as a remedial agent, appeared to me the most likely to stop the ruthless progress of destruction, which pulmonary consumption has effected and is still effecting on man.”

The only remark we shall make on this passage is, that we are quite at a loss to understand on what principle the properties of an agent being “unknown,” should have led any one to infer that it was capable of producing certain powerful and beneficial effects.

The following is the Doctor's mode of using it.

“I administer naphtha three times a day, in doses of fifteen drops for an adult mixed with a table spoonful of water, which is proportionably decreased according as the patient ap-

* Animal matter	98·15
Muriate of soda	
Phosphate of lime	
Carbonate of lime	1·85
Oxide of iron, a trace of)	

proaches youth. After the second or third day, I increase the dose by about one fourth; regulating its increase or decrease, according to the absence or presence of nausea, sickness, or any other untoward symptom arising out of its use. As the disease advances, I increase the dose to forty and even fifty drops, and administer it four times a day instead of three times."

He also informs us that he has employed it in the form of inhalation "with considerable benefit."

Of course, in a question of this kind, every thing depends upon the facts—upon the cases. Thirty-seven such are detailed, but we must confess that to us they are not satisfactory. It is impossible for any reader to know positively whether the patients laboured under genuine phthisis, but he may know whether the details are clear and satisfactory or not. Now with respect to the cases in question we do not think them at all convincing, and we subjoin the third case, because it is very short, and will thus in a very brief space shew our readers the kind of details which are thought sufficient.

"Eliza Dunn, a married woman, aged twenty-seven, residing at 14, James Street, Camden Town, had lost two of her sisters from consumption, and was admitted under my care the second of March, 1843. She had two children living, was now pregnant, and had been subject to frequent miscarriage. During the winters of the last nine years, she had been attacked with cough, and found that it increased during pregnancy. Cough, expectoration, and difficulty of breathing were severe, and though her general health was good, she had wasted considerably in flesh, which was the more immediate cause of her seeking medical relief. Percussion elicited rather a dull sound over both clavicular regions, where the respiratory murmur was harsh. After taking fifteen drops of naphtha, three times a day, for seven days, she was very much better; for the cough and expectoration had subsided, and the respiratory murmur had improved, and percussion yielded a dull sound only at the external end of the left clavicle. On the thirtieth of March, being the twenty-eighth day of her using the naphtha, she was quite well, and the signs from percussion and auscultation were natural."

We fear the reputation of naphtha will prove very volatile, and speedily evaporate.

Lectures on the Principles and Practice of Physic, delivered at King's College, London. By THOMAS WATSON, M.D. Fellow of the Royal College of Physicians, Physician to the Middlesex Hospital, and formerly Fellow of St. John's College, Cambridge. In two volumes. Parker, 1843.

To the reader of this journal no introduction to Dr. Watson's Lectures can be necessary, as he must already be familiar with them. We shall therefore confine ourselves to recommending them as forming an excellent system of medicine, embracing all the points necessary to be known, and those described and discussed in the clearest and most satisfactory manner.

On Ankylosis, or Stiff-Joint: a Practical Treatise on the Contractions and Deformities resulting from Diseases of Joints. By W. J. LITTLE, M.D. London, 1843. 8vo. pp. 145.

THE present treatise may be considered as a supplement to Dr. Little's valuable work on club-foot. Among the subjects discussed in it are ankylosis of the hip, knee, ankle, tarsal, and metatarsal bones, phalanges of the toes, lower jaw, vertebrae, shoulder, elbow, wrist, and fingers. The book comprises the history of thirty-one cases, and is illustrated with thirty-two woodcuts. Dr. Little has again made a useful addition to surgical literature.

MEDICAL GAZETTE.

Friday, October 6, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE OPENING SESSION.

THE academic session has opened, and the students who have begun the special business of their lives, are fairly embarked in their new and interesting course.

The teachers in their introductory

lectures have explained the objects which they propose to bring before them, the difficulties which lie in their way, and the general plan on which they intend to proceed. Each has shewn the value of his particular subject of instruction, and its general bearing on the art which his pupils are to practise. Each has described, according to his own peculiar views and temperament, the qualities which obtain success, the defects which endanger it, the rewards which attend it. Each has offered solid counsel, friendly advice, cheering encouragement. The teacher and pupil have entered into their mutual compact; good will and confidence mark their intercourse. Hearty greetings have passed between those once fellow students and companions, but long separated, who have enjoyed once more the gathering in the schools of their youth, while they present their sons and their pupils to men whom they have hardly met since they themselves were students. It is an occasion full of interest to all. The man of mature age recalls the temptations of his youth, and longs to impart to the young the fruits of his hard earned experience. As he surveys the benches filled with his old competitors, his thoughts revert to the past, and he remembers the qualities and the habits which formerly distinguished those whom he recognises, and he traces to these qualities the various kinds and degrees of success which have attended each in after life. He sees the young man of polished manners, of promising talent, of ready wit, become either successful and happy, or faded and discontented; the man of slow apprehension, of unready memory, of ungainly deportment, either contented with respectable mediocrity, or bearing steadily and phlegmatically the rewards which have followed his labours; he sees those who as youths were accounted

wits, sunk into coxcombs, or risen into geniuses. But amidst the great differences which appear to have resulted from apparently similar endowments, and the no less remarkable similarity which has followed remarkable differences, one quality may be relied on as having been present in all who have succeeded, and been wanting in all who have failed, and that is—diligence; persevering unshaken diligence. This inestimable quality, which the shallow and the conceited are apt to think produces monotony and sameness in the character—to be unworthy of the brilliant, and only a desirable for the dull, is on the contrary the very essential element of variety, it develops all the peculiarities of genius, and gives to each the lustre which distinguishes it; as gems when first dug are barely distinguishable from each other, the labour of the jeweller has displayed in each the tint and the water which determines its value.

The involuntary question of all, when a man is brought first under our notice, is, what *can* he do? when we continue to observe him we ask, what *does* he do? and when the great fact of his life has gone forward, what *has* he done? It is so with our inquiries concerning ourselves, and could we group the three questions together in early life, and determine to have each answered to the best of our ability in its turn, we should have taken the important step towards accomplishing the several ends of our existence; but it is not so with us, we entertain but one of the questions at a time, and that one we pursue as if there were no other, and the answer to each can be given only when it is too late to be of use—of use, that is, to ourselves—and then we try to make it of use to others, but they are all too busy answering each the question of his own time to attend to us—and so the great sphinx-riddle goes on un-

answered and unanswerable, in prospective on the whole, though clear as day when we look back on its several parts.

Now, men who have been great in any art whatever have answered each of these questions prospectively. Byron and Dante, and others before them, had to make verses; and Michael Angelo, Canova, &c. to make pictures and statues. Byron could not dance, nor ride, though he thought he could—at least, so says Lady Blessington; but he could row, sail, swim, fight, make love, and other things. In his youth, he asked, with the greatest eagerness, the question “What can I do that I like?” One of his favourite answers was, that he could make verses; and he did so—rather badly at first—but the Scotch reviewers mended his poetry at the expense of his temper, and after that what *did* he do? he still rowed, sailed, swam, and soon, but chiefly and untiringly he made verses, and very good ones he made at last; for his sailing, his swimming, nay, his very love-making, were all made subservient to this one object. Wilkie, when young, found he could draw household implements and odd faces, and could play on the fiddle, and he soon found that he had to paint pictures for dear life. So to work these men went—they chiselled, and wrote, and painted again and again. Wilkie’s diary tells us little else than that he painted all the week, and went to church on Sunday. He, then, Byron, and others, answered the third question, “What have they done?” to the entire satisfaction of all the world; and their answers are hung up in the Tribune, the Vatican, and other conspicuous places.

All who do great things have answered these questions well, though some, it may be, without knowing it. The business of education, the prime duty of teachers, is to point out the

way of getting the right answers in the right order; to arrange what they teach with a view to what is to follow. Whatever knowledge does not serve this purpose it is pity to have learnt. The physical qualities of the *Materia Medica* may be known to a labourer in a drug warehouse, and human anatomy to an observant grave-digger; but the physician and surgeon want them for therapeutics, and for operations. And the main business of learning, the prime duty of the student, that to which we would earnestly and affectionately exhort him, is to look well to the future value of his present pursuits—to take the opinions of the experienced as to the employment of his time and powers—that his youth may be spent judiciously in inquiring what he can do, his active life profitably in what he does do, and his old age honourably in the contemplation of what he has done.

It is often wished that the knowledge of one man could be bequeathed entire to another, and that the progress of science might be rapid and uninterrupted; but what this would do for science, and for mankind generally, would also be done for individuals if the powers and acquirements of each period of life could be rendered wholly available to the next. The child being “father to the man,” what giants might thus be begotten, but the limits placed by Almighty Providence are not less wise in the one case than in the other; and when we indulge in such Titanic aspirations, it may truly be said, “*Cælum ipsum petimus stultitiâ;*” but a healthy desire for a perfection which is abstractedly unattainable, is not only innocent, but a wholesome stimulus to obtaining that which is practically within our reach; and we may laudably strive in detail after that which the wildest dreams of fancy cannot hope to realise entire. The great advantage

of special and well-directed study over that which is irregular and desultory, is, that its tendency is uniformly progressive, and its results, in their kind and degree, useful and satisfactory.

In an experimental art like ours especially, discipline of such a course is invaluable, and the benefit certain. We observe this when circumstances allow of genius taking its own bent; following its eager yet steady course. It weaves and moulds all surrounding objects to its own purposes. Difficulties, if not insuperable—and how few difficulties are so to true genius—only supply training and discipline. Genius, however, is the lot of but few: talents, few or many, are given to all; and when to some they prove wholly useless and unprofitable, the fault lies in their direction and application.

We have reached a critical period in science and art. Many old views, on which practice has been founded, seem likely to be superseded by new ones; and many that have been long forgotten are being revived as novelties. Not only public opinion has received some shocks, more than enough to unsettle its ill-grounded notions on professional subjects, but professional opinion likewise rests but loosely on many of its fundamental points. Doubt, the parent of belief, has produced an unusual farrow of credulities, fed and fattened without greatly reducing the bulk of their dam. We are called on to believe implicitly in every thing but what has the progressive experience of ages on its side. Now in such times, such “awful crises,” which philosophers of the *poco curante* sort tell us happen every ten years or oftener, the man of solid learning and attentive habits will in the long run have an immense advantage. “Schools and the schoolmen” will always be more or less sneered at; but it is remarkable that while common sense

points out that those who know most of what is taught in the schools have the best right to criticise their lore, it is precisely those who know least about them—the least learned—who are most flippant on the subject.

Truly the Sydenham Society is likely to be very useful: it will do a world of good to our profession to get a little more *learning* into it; men of really original and powerful minds will be made more original and more powerful. Those who are neither the one nor the other may perhaps by study find out their deficiencies; or if this be too much to hope for, the number of those who think too highly of them will be diminished, and that will be something gained.

Clever theorists, who are unlearned, often do the same service to science that unprincipled demagogues do for a state—they clear away much rubbish by the reforms they effect, but they also destroy much that is good, the value of which was unknown to them; and no successful revolutionist ever failed to discover this sooner or later: some have honestly avowed this conviction, but all have betrayed it. Clever men who *are* learned move more slowly; their reforms, when they venture on any, are conservative, not destructive; yet their progress in the end is often greater.

For the student there is but one safe course—to strive to know all that is taught him; he will have much to teach himself after all is learnt that can be taught him by others, and if he has real genius, his subsequent flight will be none the worse for his taking wing from the solid vantage ground of progressive experience, even though the materials which compose it be held together by a theory which is doomed shortly to crumble away.

TWO LATE CORONERS' INQUESTS.

As inquisition was held on the 30th ult. and 2d inst., before Mr. Baker, on the body of Francis Chalkley, aged 40. It appears, that on the 9th of August he took six grains of blue pill, and three of calomel, which produced a mercurial fever, under which he sank, and died on the 26th of September.

That so small a dose should produce so violent an effect, though extraordinary, is not unparalleled. Thus, we find it stated by Dr. Christison that "Fifteen grains of blue-pill, taken in three doses, one every night, have excited fatal salivation. Nay, two grains of calomel have caused pyalism, extensive ulceration, exfoliation of the lower jaw, and death*."

In the report of the first day's inquest (Times, Oct. 2d), a medical witness was made to say that the dose was "inordinate," and sufficient for at least three persons. This must surely be a mistake of the reporter's; for, not to mention that Sydenham recommends a scruple dose of calomel, the large quantities given in our own day by the surgeons of India, and others, suffice to show that the dose administered to Chalkley was within very safe limits. We are far from recommending the practice of pushing the doses of mercurial remedies, but six grains of blue-pill, *plus* three of calomel, are probably not more than the every-day dose of five grains of calomel.

Mr. Dickinson, who prescribed the medicine, is confined for debt in Whitecross Street Prison, where he occasionally officiates for Mr. Wadd, the visiting surgeon. He does not possess the diploma of the College of Surgeons, nor is he a Licentiate of the Apothecaries' Company; but he is described by Mr. Wadd, in his evidence, as a highly respectable man, and formerly an apothecary and a general practitioner at Egham. We therefore conjecture that he may have been in practice before 1815, and thus be a qualified practitioner, though without a license. Mr. Wadd "thought that the dose might have been given twice instead of once."

Since writing the above, we have read a very sensible letter by Mr.

Dickinson, in the *Times* of Oct. 4th: Mr. Dickinson has been in practice upwards of thirty years, and may therefore be a qualified practitioner though without a diploma, as we had conjectured. The salivation was, no doubt, owing to a remarkable idiosyncrasy; unless we attribute it to some pills of unknown composition which the deceased took afterwards, as he confessed to Mr. Dickinson.

The jury brought in a verdict of natural death, but called the remedy administered "an overdose of strong medicine."

Another inquest was held on the 30th ult. before Mr. Baker, at Haggerstone, on the body of Mary Haynes, aged 25.

Her husband, following the instructions of one of those hideous books engendered by the theories of Malthus, had given her large doses of some medicine in order to procure abortion. It appeared, on a post-mortem examination, that she was not pregnant, and that she died of sanguineous apoplexy, and inflammation of the stomach.

The chief point of interest in this inquest is, *what was the poison administered?* The witnesses in the report (Times, Oct. 2d), all call it the sulphate of potass. Now, although sulphate of potass is a harmless medicine in small doses, it is possible that it may cause death when administered without limit. Even common table-salt has been fatal in the prodigious doses in which it has been given for worms in domestic practice. The man Haynes bought a quarter of a pound a fortnight before her death, which she took in small quantities; and then gave her two ounces more on Tuesday (Sept. 26th) and two more on Wednesday; she died early in the morning of Thursday the 28th.

Most readers would conjecture that the medicine meant was the *sulphuret of potass*; but had Mary Haynes taken two ounces of this violent poison on Tuesday, and two more on Wednesday, would she have been in good spirits and laughing on Wednesday evening, as Sarah Reynolds, one of the witnesses, testifies?

In the two cases recorded by Dr. Christison, where sulphuret of potass proved fatal, death took place in less than fifteen minutes, and in one the

* Christison on Poisons, 1st Edit. p. 303.

dose was about three drachms.* The two surgeons who opened the body were Mr. M. Pickering, and Mr. G. W. H. Coward. The former calls the medicine *sulphate* of potass, but says "its component parts are equal portions of sulphur and potass," which is a description of the *sulphuret* of potass.

Mr. Coward, on the other hand, says "the sulphate of potass did not come under the denomination of a poison, but was a violent purgative, which required to be administered with great care. Witness believed that two ounces of the drug would cause sickness, from which inflammation might arise, and the blood flowing to the head might then cause apoplexy. There could be no doubt that the drug was the remote cause of death."

We await the termination of the inquiry. If it should turn out that the poison was the sulphate of potass (as we are inclined to think it was) this will be the first case on record of poisoning by that neutral salt. If it should prove to be the sulphuret of potass, it will be equally singular that such enormous doses should have been required for a fatal effect.

Since the above was written, our supposition that the salt was *sulphate* of potass has been substantiated by witnesses at the adjourned inquest. On Tuesday, the 3d inst. the jury brought in a verdict of wilful murder against William Haynes.

How much it is to be regretted that the evidence at Coroners' Inquests is not reported by medical practitioners! The evidence for a single year only would be a mine of instruction in toxicology.

CLINICAL REPORTS OF CASES

TREATED AT THE GLASGOW EYE
INFIRMARY.

BY WILLIAM MACKENZIE, M.D.

Case of lenticular cataract, treated by extraction—Section of the cornea made with a moveable needle-knife—Remarks on needle-knives.

CASE.—No. 12315, Aug. 4th, 1842.—John Wylie, aged 62, a weaver. Fully formed lenticular cataract in left eye; same disease in right eye, but not so far advanced. Both retine sensibile. Slight strabismus diver-

gens of left eye. Says his mother, and two sisters of his father, had cataract.

12th.—The patient being laid on his back, the left cornea was transfixed by the needle of an instrument, in which a needle is combined with a moveable extraction-knife; the knife was then moved forwards, and the section made, parallel to the upper edge of the cornea. The capsule-needle was introduced, and the capsule divided. A part of the surface of the cataract was soft; the rest, being nearly of the natural size of the lens, was firm, and was easily extracted. The cornea was now gently rubbed, through the medium of the upper lid, till the pupil was seen to be of a natural size, and in its natural place. The eyelids, on each side, were brought together with a stripe of court plaster.

14th.—No pain.

15th.—Eye looks well.

21st.—Flap of cornea in its natural situation. Wound does not appear to be united. Pupil a little irregular. Vision good.

Appl. Extr. Belladon. ad supercil. sinist.

22d.—Cornea hazy. Says things appear very white.

Cap. Pil. Calomel. gr. ij. et Op. gr. ss. m. et v.

30th.—Capsule pretty opaque. Pupil irregular, and drawn back towards capsule. With a double convex lens tells the hour on a watch with left eye.

REMARKS.—No further reports appear in the journal. Previously to last report the wound of the cornea had perfectly united. He was soon after dismissed, cured by operation, being able with a cataract-glass to read an ordinary type. The iritis which took place in this case was attended with no pain, and scarcely any external inflammation. It left the pupil a little irregular, and the capsule partially opaque.

The section of the cornea being made with an instrument not in common use, I may take this opportunity of making some remarks on *needle-knives*. As the name imports, these instruments combine the qualities of a needle and a knife. They are of two sorts, the *fixed* and the *moveable*; and the first invention of both sorts we owe to the same surgeon, Pallucci*.

David, who, though not the inventor of extraction, was the first to practise that operation as an ordinary means of removing cataract, began the section of the cornea at the middle of its lower edge, with an instrument like a lancet. This must have permitted the aqueous humour to escape. He then insinuated into the wound another lancet, blunt at the point, but cutting on the

* Christison on Poisons, p. 171.

* Descriptio Novi Instrumenti pro cura Cataractæ, nuper inventi ac exhibiti a Nat. Joseph. Pallucci. Vienna, 1763.

edges; and with this he enlarged the incision a little bit towards the nose, and a little bit towards the temple. He invented two pairs of scissors for the completion of the section. Each pair was doubly bent, the one so that it was fitted for completing the section on the nasal side of the eye, and the other on the temporal side. Thus, with four different instruments, Daviel completed a semicircular section of the cornea. It was probably the fear of wounding the iris which led him to this cautious and complicated mode of operating. He does not appear to have had the least idea that the same section could have been much more easily accomplished by one stroke of a knife, carried across the anterior chamber. The effect of the refraction of the aqueous humour and cornea is to make the iris appear convex, and nearer to the cornea than it really is. Perhaps this may have misled Daviel from the proper mode of opening the cornea.

Two reasons must have weighed with succeeding operators to employ a different mode of operating from that of Daviel. The one, the complexity and difficulty of such a proceeding; for not only are the instruments by far too numerous for so simple an incision, but it is difficult to effect the purpose intended, after the aqueous humour has made its escape, the cornea lost its tension, and the iris is pressing into the wound. The other, the danger of such a haggled, irregular, and partly bruised wound not healing; for an incision of the cornea which is sawn, and not cut at the first stroke, or still worse which is clipped, does not heal in general by the first intention; but its edges swell and suppurate, close by a tedious process, and leave a broad and injurious cicatrix.

Whether Pallucci was the first to think of cutting the cornea with a single instrument, and by a single stroke, I do not know. The instrument which he invented for that purpose was a needle-knife, of the *fixed* kind. The knife part was triangular, not unlike Beer's knife, only not so broad, while the point of it was prolonged into a lance-shaped needle. Having transfixed the cornea with

the needle part of this instrument, by a simple progression towards the nose and over its arch, the knife effected a semicircular incision of the cornea. The disadvantage of such an instrument (and both Siegerist and Weidmann have recommended fixed needle-knives) is, that the point of the needle, unless the handle of the instrument is kept very much back towards the temple, comes into contact with the side of the nose, makes the patient start, and may thus ruin the operation.

It was probably this disadvantage of the *fixed* needle-knife which led its ingenious inventor to the contrivance of a *moveable* one. This consisted of a needle, fixed in the handle, and grooved on its lower edge, while along the groove there played a knife, which, by pressure on a knob at the extremity of the handle, could be moved forwards. With the needle, then, which formed part of this instrument, Pallucci transfixed the cornea, and then, keeping the needle steady, he moved the knife on, till the section was completed.

It was from Pallucci's moveable needle-knife that I took the hint to have the one made with which I operated on Wylie. I omitted the groove along the lower edge of the needle, as I thought that was likely to allow the aqueous humour to escape; but in other respects there is no essential difference between the two instruments. The needle part I made broader and longer; broader, so that in transfixing the cornea with it I might accomplish a certain considerable portion of the section; longer, that there might be less risk of the point of the needle slipping out of the nasal part of the cornea when I came to push on the knife. Pallucci's knife was convex on the edge; I made mine straight, exactly like Beer's knife, that it might traverse the cornea with the least possible resistance.

Figure 1 shows the knife I used, reduced one-third, with the knife retracted, and its cutting edge directed upwards, as it will be held when the operator means to open the upper half of the cornea.

Fig. 1.

Figure 2 shows the knife pushed forwards, as it is when the section is completed.

Fig. 2.

The nail A, screwed into the back of the knife, serves to keep the edges of the needle and the knife in contact, and travels along a slit to B. The thumb, pressing on the verrouil, C, moves the knife forwards, in making the section.

The following are some of the advantages which appear to attach themselves to such a moveable needle-knife.

1. It is much easier to traverse the anterior chamber with a needle than a knife.

2. It is much easier to perform the counter-punctuation of the cornea accurately with a needle than a knife; and how much depends on counter-punctuating well, every operator is aware. The size and form of the section, depend, in a great measure, on exact counter-punctuation.

3. There is less risk of the aqueous humour being evacuated in traversing the cornea with a needle than with a knife.

4. The cornea being transfixed by the needle part of the instrument, the knife moves along a director, with perfect steadiness and certainty, and completes a regular section of the cornea, at a definite distance from its edge.

The chief disadvantage attending the use of a moveable needle-knife (and which, though it did not occur in the least in Wylie's case, I have experienced on some subsequent occasions), is, that the pressure, necessary for moving on the knife to make the section, is apt to be accompanied with a retrograde movement of the needle, so much so that it slips out of the nasal side of the cornea, and allows the aqueous humour to escape. This danger may be partly obviated by having the instrument exceedingly well finished, so that the knife moves sweetly along the needle, and yet is not at all loose or unsteady. It is difficult to adapt the two pieces, of which the instrument consists, to one another with perfect accuracy, and yet slide along each other with the necessary freedom.

It occurred to me, soon after I began to try the moveable needle-knife, that if, instead of the needle and the knife forming part of the same plane, they were placed side by side, the motion of the knife might be rendered steadier and easier. I was confirmed in this notion by the examination of an instrument, invented by Dr. Louis Stromeyer, for artificial pupil, and called by him a *korrektom*. It is in fact a needle-knife, the mechanism of which is extremely neat and well-finished. I therefore ordered a needle-knife to be made, pretty much like Professor Jäger's double knife, only that instead of two knives running side by side, there was to be a needle and a knife. The instrument, so modified, I have hitherto had no opportunity of trying. I may mention, that Dr. Stromeyer's instrument is a

knife for at once making a section of the cornea, and cutting out an artificial pupil. He describes and figures it in a pamphlet, published at Angsburg in 1842, and entitled, "*Das Korrektom*." The needle is grooved along the side which regards the knife, for the purpose of allowing the aqueous humour to escape, and the iris to fall forwards, so as to be divided by the knife, which, on being pushed on, makes a section of the cornea, and cuts fairly out a piece of the iris. Of its merits as an instrument for thus forming an artificial pupil by central excision I can say nothing. For the sight of Dr. Stromeyer's instrument, and the pamphlet in which it is described, I am indebted to my friend Dr. Hamilton, of Edinburgh.

The chief objection to a needle-knife for making the section of the cornea in extraction, in which the needle and the knife do not lie in the same plane, but side by side, will be the thickness of the instrument, and the danger, that, by its thickness, it may press so much on the aqueous humour, and through the aqueous humour on the lens, and through the lens on the vitreous humour, as to cause rupture of the hyaloid membrane before the section is completed, so that just as the section is finished the lens and part of the vitreous humour bolt together out of the eye. This is a danger which attaches itself even to a common cataract-knife, if it be too thick, if the aqueous humour be not allowed to escape before finishing the section, and especially if the subject be old, and the hyaloid membrane weak. How much more likely will it be to occur, if, to the ordinary thickness of a cataract-knife, there is added that of a needle!

Some time after I had given an order to the cutler for a new needle-knife of the kind last mentioned, I met with an account, in the *Annales d'Oculistique* for April 1843, of an instrument exactly similar, the invention of Professor Blasius, of Halle. Having made the punctuation with the needle, he follows the plan of Wenzel, dipping the point of the instrument into the pupil, and opening the capsule; he then effects the counter-punctuation, pushes on the knife, and completes the section. The lens often follows, we are told, without any pressure on the eye, and of course without the introduction of any second instrument for the purpose of performing what is commonly called the *second* period of the operation. The supposed advantages of conducting the operation in Professor Blasius's way, and with his needle-knife, are set forth in a thesis by Dr. Van den Porten, entitled, *Dissertatio de Cataractæ Extractione, adjecta nova extrahendi ratione*. I may notice, that, as Professor Blasius always keeps the needle towards the iris, he requires two

instruments, one for the right and another for the left eye, whereas the needle-knife with which I operated on Wylie answers for either eye.

REMARKS ON

DR. BIRD'S REPLY TO MR. CAMPLIN.

To the Editor of the Medical Gazette.

SIR,

ON looking through your valuable number of to-day, and finding no observation whatever, from the pen of Mr. Camplin, relative to the very extraordinary reception of, and reply to, his letter in the *MEDICAL GAZETTE* of the 1st inst. by Dr. F. Bird, I am induced, notwithstanding the probable charge of needless quixotism for my pains, to offer a few words defensive of my too retiring neighbour and friend.

I must confess that after the very proper and conscientious letter of Mr. C. (unostentatious in itself, and seeking only "to render honour to whom honour was due,") I was romantic enough to have hoped that, when noticed by Dr. Bird, it would have been in the spirit of thankfulness for the mild rebuke of an older and more considerate practitioner, and been followed by a prompt and manly acknowledgment of an omission, for which so easy and effective atonement could *instantly* have been made; but—alas! for modern optimism—Dr. B.'s anxiety for personal distinction being greater than his solicitude for moral elevation, he became irritated by reproof, gentle as it was, and, with a too prevalent sophistry, tried to throw a doubt over the "motive" which his egotism would not allow him to respect; and in turn has assailed Mr. Camplin in a manner at once disingenuous and irrelevant.

Now, having had the gratification of personally assisting at both of Mr. Walne's cases, I must beg to make one or two very brief remarks upon that detailed by Dr. Bird (No. 47, Aug. 18), and, in so doing, I shall be most happy to do that justice to the Dr.'s claim to originality, which his own want of boldness has prevented him from doing himself. Imprimis, then, the preparatory treatment, abstinence, enema, pills (to a grain), the exploratory incision, &c. were so identical with the preliminaries of Mr. Walne, more especially those of his second case (then unpublished), that I should have imagined Dr. Bird had obtained them from that gentleman himself, had not the "obscure little paragraph" of Mr. Camplin induced the doctor to inform your readers, that he, Dr. B. "happened to be in attendance upon a lady, one of whose medical attendants had frequent opportunities of watching Mr. Walne's (second) patient, and that he thus *occasionally* heard of the progress of the case." Now,

what pity that Dr. Bird's want of boldness prevented him from informing them that this lady *resided in the same house* with Mr. W.'s patient, and that he there *personally* and *daily* obtained his information; what pity his want of boldness prevented him from making his inquiries openly of Mr. Walne himself, whose *penumbra* he must so frequently have been.

2d. The length of the incision and puncture of the cyst differ very decidedly from the practice pursued by Dr. Clay and Mr. Walne; and the peculiarly happy medium so energetically claimed by Dr. B. between the "unnecessary large incision" and the inch and a half cut, has just this degree of novelty, that, in a case of twenty years since, alluded to in Mr. Walne's first paper, but ingeniously overlooked by Dr. Bird on his "careful perusal," the incision was of $3\frac{1}{2}$ inches; thus giving a *problematical* half inch to the Dr.'s boldness of improvement.

3d. The triple ligature, and succeeding steps of the operation, were closely imitative of Mr. W.'s proceedings, whilst the only other prominent deviation from so good an example shews how truly Dr. B. may assert his having "profited so little by the recorded cases." I allude to the substitution of the water dressing and *few* sutures, for the comparatively close stitches, and lint and plaster support, so carefully applied by the antecedent operator, and which, if adopted by this half-and-half copyist, would in all probability have saved him the mortification of subsequently viewing his patient's intestine outside of the abdomen.

In the after-treatment of the case, the choice of the anodyne, the dietetic character, &c. are unacknowledged imitations; the originality of this portion only amounting to the evincing that, if the printed statement be not defective, then the treatment most assuredly was. *Exempli gratia*: on the morning after the operation we have this entry. "5 A.M.—Complains much of pain at the lower part of the abdomen; ξxij . of high coloured turbid urine drawn off by catheter." Now I can only here surmise that Dr. Bird having omitted to evacuate the bladder of the patient before he retired the previous night, was summoned at this early hour to remedy the effects of such inadvertency. I confess this may be only surmise. But again: "10 P.M.—Heat of skin, &c. &c.: ξxij . of urine drawn off by catheter." Here is an interval of *seventeen hours*, during which the patient is ostensibly exposed to the chance of whatever irritation might arise from so protracted a retention. Surely this borders closely upon the "absurdity of refusing to learn by recorded experience."

Of Dr. F. Bird's parting call upon Mr. Camplin, to inform him "where he (the Dr.) can meet with any addition he (Mr. C.)

has ever made to medical science," the petulance is about on a par with its irrelevancy. Unlucky call! Why, sir, were this the first time that Mr. Camplin had put pen to paper in relation to professional advancement, he has, in this brief exposé, established his claim to the gratitude of the rising generation, by bringing forward additional proof that in the practice of surgery "honesty is the best policy," and that in the science of *medical ornithology* your readers must be careful to avoid mistaking borrowed feathers for natural plumage.

With the best apology for my intrusion on your pages—the sincere desire of seeing the moral character of the profession maintained and exalted—I beg leave to subscribe myself, yours very obediently,

CHARLES LAW.

VIVISECTION.

To the Editor of the Medical Gazette.

SIR,

SINCE my remarks on Vivisection appeared in your journal, I have received communications, by which I find that the profession take more interest in the question than I had anticipated, and that Dr. Hull and myself are by no means so singular in our views as I had feared.

As I am quite ready to redeem the pledge I gave in my letter to you, I would suggest, in order to economize the space of your columns, and the time of the contributors to this discussion, that gentlemen who think that vivisection is a profitable or philosophical mode of inquiry, should point out any set of experiments which they may consider it difficult or impossible to dispose of in the manner which I have asserted. If I were to select them, there might be perpetual cavil at the *selection*, or if I chose the more recent, as those of my contemporaries, objections of another kind might be urged. But if the experiments by which the general question is to be tested are chosen by other people, I am responsible only for the manner in which I proceed to analyse their influence on the progress of pathological science, as applied to the cure of diseases. In the meantime, I think the passages to which I referred you seem as good an opening as I could give; and if no one sends you any thing that you like better, or if the article is too long for your columns, I will try to get it admitted in some of the larger periodicals.

I have the honour to be, sir,

Your obedient servant,

GEORGE MACILWAIN.*

9, Argyle Place, Sept. 26, 1843.

* ERRATUM.—In my last letter, line 11, for "instructive" read "inductive."

SCHOOL OF PHARMACY.

THE qualified Chemist is entitled to adequate recompense, not only for the labour or exercising his skill, but also for the labour which he has previously undergone in acquiring it. His time constitutes a portion of his capital; and its value must be estimated before the *cost* price of his goods can be correctly ascertained. In making this calculation, a variety of circumstances relating to the nature and peculiarities of his business must be taken into consideration; but the hypothesis upon which all our arguments are founded, is the presumption, that all the individuals composing the body are qualified. In order to make our hypothesis correct, we must defer the main argument for the present, and call the attention of our readers to the means by which alone the desired improvement in our character and position is likely to be effected.

The School of Pharmacy is the ladder by which we may hope to ascend to our proper place in the profession. The existence of such an institution is a practical demonstration of the fact, that our business is not merely a mechanical trade, but that it requires in those who follow it a certain amount of mental cultivation and scientific knowledge. That many members of our body are thus qualified we fully believe; but the nature and extent of such qualifications of each individual, as well as the means by which they have been acquired, are known only to himself. The branches of study with which the pharmaceutical chemist should make himself acquainted have not until lately been clearly defined, and are not even now insisted upon. In fact, the only class of Pharmacutists who are obliged by law to pass an examination in Pharmacy are the Apothecaries. The chemists are left at liberty to use their own discretion in the matter; those who possess the means and the inclination to study their business as a profession, learn just as much as is convenient to each individual, and no more; others trust in the blue and red bottles, and all are classed together as Chemists and Druggists.

But this state of things cannot continue. The responsibility which rests on those who prepare and compound medicines is felt by the public; and the time must soon arrive in which the educated Chemist, who has made himself acquainted with the principles and sciences, will no longer be confounded with the Chandler, the Grocer, or the Oilman.

However humiliating it may be to acknowledge that imperfections exist among us, it must be a source of satisfaction to every one who feels interested in the credit of his profession, to reflect, that the whole of the

operations which are now in progress for the advancement of education in our body, emanate from ourselves. It must also be recollected, that whatever stigma may be thought to exist, cannot belong to those who are engaged in the work of improvement, but to the disaffected who are contented to remain stationary, while every other class of men is advancing with the times. And since we have every reason to believe that a very large proportion of our number cordially unite in the undertaking, and feel themselves identified in its results, it is not too much to expect, that all our members, in proportion to the opportunity within their reach, will co-operate in promoting the prosperity of the *School of Pharmacy*.—*Pharmaceutical Journal*.

NEW MODE OF DETECTING ARSENIC.

A SHORT time since Professor Reinsch proposed an entirely new method of detecting arsenic, which consists in acidulating any suspected fluid with hydrochloric acid, and heating a thin plate of bright copper in it, upon which the arsenic is deposited in a thin metallic crust, and then separating the arsenic from the copper, in the state of oxide, by subjecting the copper to a low red heat in a glass tube. Organic fluids and solids may be prepared for this process, by boiling them for half an hour with a little hydrochloric acid, solid matters being cut into shreds, sufficient water being added to let the ebullition go on quietly. Continue the boiling until the solids are dissolved, or reduced to minute division. Nothing can be more easy than the method of Reinsch. It is also exceedingly delicate; for it will detect a 250,000th part of arsenic in a fluid, and it does not leave any arsenic in the subject of analysis which can be detected by any other means, even by the delicate process of Mr. Marsh. I have lately employed it as the means of furnishing irrefragable evidence in criminal inquiries.

The separation of arsenic upon copper, from a solution, by means of hydrochloric acid and heat, is a new fact in chemistry; and the experiment furnishes a test so far, that if the copper be not tarnished, arsenic cannot be present. But Reinsch's discovery cannot be regarded as a *positive* test, because as he himself has pointed out, bismuth, tin, zinc, and, above all, antimony, will, under the same circumstances, yield a coating of copper sufficiently similar to render it necessary that the deposit be examined other than by the eye only. Reinsch's process, however, is of far greater value than if it had merely presented a new test for arsenic. It constitutes the easiest and most secure

mode of so separating arsenic from complex mixture, as to enable experimentalists to apply to the metal any of the tests for arsenic already known; and, in my opinion, no method of testing for it approaches the following in conclusiveness:—Cut the copper on which the arsenic is deposited into small chips, so that they may be easily packed at the bottom of a small glass tube. Apply a low red heat. A white crystalline powder sublimes, in which, in the sunshine, or with a candle near it, a magnifier of five powers will show the equilateral triangles composing the facets of the octahedral crystals, which are formed by arsenious acid when it sublimes. Sometimes the three equal angles, composing a corner of the octahedron, may be seen by turning the glass in various directions. If triangular facets cannot be distinguished, owing to the minuteness of the crystals, then shake out the copper chips, close the tube with the finger, and heat the sublimed powder over a very minute spirit-lamp flame, chasing it up and down the tube until crystals of adequate size are formed. Next boil a little distilled water in the tube over the part where the crystalline powder is collected, and, when the solution is cold, divide it into three parts, to be tested with ammoniacal nitrate of silver, ammoniacal sulphate of copper, and sulphuretted hydrogen, either in the state of gas or dissolved in water. I am surprised that during the last four or five years, neither Orfila, nor M. Lassaigne, nor Liebig, nor Mr. L. Thomson, nor Mr. Watson, nor Mr. Marsh himself, nor any other experimentalist, excepting in Scotland, has thought of applying as a test of an arsenical crust, the conclusive process described above, and first suggested to me in 1826, by the late Dr. Turner, which consists in converting the metal into the oxide in such a way as to allow the form of its crystals to be determined. The method has been in constant use in medico-legal researches in Scotland. Yet, what other method is so satisfactory? What substance, other than arsenic, yields the white sublimate with triangular facets, or leaves the substance in such subjection to so many excellent tests?

In boiling substances in the weak hydrochloric acid, a decided excess of acid must always be present,—two fluid drachms to every eight ounces of liquid; but if the matter be animal texture in decay, much more acid may be necessary, owing to the presence of ammonia, which gradually neutralizes the acid as the solution goes on. Filtration of the fluid after the acid has acted sufficiently, seems advisable, otherwise organic particles may attach themselves to the copper, and give rise to empyreuma, when the metallic arsenic is driven off by heat. When the arsenic in the fluid is supposed

to be small, nearly half an hour should elapse before the copper or copper-leaf is removed. Before applying the sulphuretted hydrogen as a test to the solution of the sublimed oxide, the solution must be acidulated with hydrochloric or acetic acid. In every case the whole process should be applied in the first instance to distilled water, acidulated with the hydrochloric acid to be employed afterwards; and if the copper be tarnished, a purer acid must be obtained, or the copper must be subjected to the subsequent steps of the process, in order to ascertain whether the tarnishing be occasioned by arsenic or not.

I have successfully employed the preceding method in two medico-legal cases, where the bodies had been buried for four months, and I consider that it must soon supersede the beautiful but much more elaborate method of Marsh.—*Dr. Christison, in Lond. and Edinb. Journ. of Medical Science*, Sept. 1843.

ON THE EMPLOYMENT OF BELLADONNA IN THE TREATMENT OF PHIMOSIS AND PARAPHIMOSIS.

By M. DE MIGNOT.

M. DE MIGNOT, having derived benefit from the application of an ointment of belladonna in cases of phimosis and paraphimosis, recommends its employment in every case before having recourse to the knife. The ointment is made in the proportion of twelve grains of the extract of belladonna to thirty grains of simple cerate, and with this the prepuce is rubbed every hour. The dilating power of the belladonna soon begins to act, and in many cases an operation may be avoided. When the inflammation is violent, and the pain intense, he recommends to add a little opium and mucilage of quince seeds.—*L'Experience*, Dec. 15, 1842; and *Edin. Med. and Surg. Journ.* Oct. 1, 1843.

SINGULAR MADNESS OF A NAVAL CAPTAIN.

HER Majesty's Brig the *Lynx*, mounting three large guns, was lately lying off the town of Cove, when her Commander, Capt. Burslem, gave the order to clear the decks for action. This was immediately done, the guns were primed and loaded, and in a few minutes after, Capt. Burslem ordered the guns to be fired upon the town. The officers next in command now consulted together, persuaded the captain to go below, secured him, and reported the affair to the Admiral of the squadron. Captain Burslem was immediately removed, and the town of Cove escaped demolition by the hands of a madman.—*Times of October 3, from the Cork Reporter*.

NOTE FROM MR. DUNN.

To the Editor of the *Medical Gazette*.

SIR,

A FATAL case of cancrum oris, complicated with measles, has occurred in my practice within the last few days, and on which a coroner's inquest has been held, from the suspicion that the child died from the effect of mercury. I think it a duty which I owe to myself and the profession to publish the case, and shall take the liberty of sending it for insertion, with your permission, in the next week's *MEDICAL GAZETTE*. The most correct report of the inquest I have seen appeared in the *Morning Post* of yesterday. I have to regret that time will not permit me to send it this week.—Your obedient servant,

ROBERT DUNN.

GULSTONIAN LECTURES,

*Delivered at the College of Physicians,
February, 1843.*

By GEORGE BUDD, M.D. F.R.S.

Professor of Medicine in King's College, London.

LECTURE II.

I COME now to consider the causes capable of exciting inflammation of the liver that terminates in suppuration and abscess.

With the view of discovering these, I have tabulated the chief circumstances of 59 cases in which one or more abscesses were found in the liver after death. 15 of these cases occurred in my own practice at the Dreadnought, in sailors, most of whom had been in the East; 15 were collected by Louis and Andral, in the hospitals of Paris; and 29 are recorded in the splendid work of Annesley, on the diseases of India. In my remarks I shall make frequent reference to the facts expressed in these tables.

In the list of causes capable of exciting suppurative inflammation of the liver, I shall place first—

1. A blow, or other mechanical injury. This, although the most obvious cause—the cause most readily discovered—is by no means a frequent one. Among the cases exhibited in the tables there is only one, a case recorded by Andral, in which the disease of the liver could be clearly traced to a blow. In this case there were two abscesses, of large size, and seated, as I suppose is usual in abscesses produced in this way, on the convex surface of the right lobe.

The rarity of inflammation and abscess from accidental injury shews how effectually the liver, when of its natural size, is shielded by the ribs.

2. A second, and far more frequent cause of abscess of the liver, is suppurative

inflammation of some vein, and the consequent contamination of the blood by pus.

Very soon after morbid anatomy began to be studied, it was discovered that in persons who die some days after a severe injury or surgical operation, collections of pus are often found in the lungs, the liver, the joints, between the muscles, and in various other parts of the body. These collections of pus form very rapidly—in some cases, in three or four days—and often with very slight local symptoms; and when occurring in the lung are strictly circumscribed, or immediately surrounded by perfectly healthy pulmonary tissue.

These circumstances suggested the notion, at one time generally received, and still held by some eminent pathologists, that the pus is not formed by a process of inflammation in the parts in which we find it, but that, having entered the circulation from the original seat of injury, it is merely *deposited* in those parts. The abscesses found in the lungs and liver in such cases have, in consequence, been very generally spoken of as *deposits* of pus.

An examination of pus through the microscope is sufficient to show that it cannot be deposited in the way supposed. Pus-globules are larger than blood-globules—according to some anatomists, twice as large—they could not then escape from the vessels without the blood-globules escaping as well. This circumstance is, perhaps, of itself, sufficient proof that the pus of those scattered abscesses is not simply *deposited* from the blood, but that it is formed, as in other cases, by a process of inflammation in the parts in which we find it.

Other and more conclusive evidence on this point has been furnished by the researches of MM. Dance and Cruveilhier. They have shewn that, although in most of such cases we find in the lungs fully-formed abscesses immediately surrounded by pulmonary tissue perfectly healthy, yet in other cases, in which death happens

earlier, instead of abscesses, we find small, circumscribed, indurated, or hepatised masses. In some instances the abscesses are formed in succession, so that in the same lung (as you see in this diagram, which I have had made from one of the plates of Cruveilhier) we find all intermediate stages between commencing induration, or hepatisation, of a small circumscribed portion of the pulmonary tissue, and a small circumscribed abscess. This circumstance did not escape the observation of Morgagni. Speaking of abscesses of the same kind that result from injuries of the head, he says—

“*Fac enim relegas quas tibi novissimè descripsi, Valsalvæ observationes. Nempe tubercula plerumque invenies sive in pulmonibus, sive in ipso etiam jecore non omnia fuisse suppurata, quin plura interdum glandulosi corporis firmitudinem adhuc referentia. Quid? Si ægro moriente, necdum ulla essent quæ pus habere inciperent.*”

And his sagacity led him from this very near to what at present seems to be the true mode of formation of these abscesses. His words are—

“*Videtur autem secundum eas observationes, quibuscum, ut puto, Molinellii conjungi potest observatio, pus in viscera aliunde invectum, non puris forma semper deponi, sed hand raro sætem nonnullas ejus particulas cum sanguine permistas, et prorsus disjunctas, in angustiis quibusdam, fortasse glandularum lymphaticarum, hæreere, easque, ut in venereorum bubonum productione fit, obstruendo, aut irritando, eoque humores præterituros retinendo distendere, et multo copiosioris quam quod advectum est, puris generationi, a rigoribus illis, et horroribus significatæ, causam præbere. Qua ratione illud quoque intelligitur, quomodo multo plus puris in visceribus, et cavis corporis sæpe deprehendatur, quam modicum vulnus dare potuisset.*”

His doctrine, then, is, that pus carried to the viscera from distant parts, is not always deposited as pus, but that often some of its globules become arrested in the narrow channels of the body, and there, by obstruction or irritation, cause congestion, and give occasion to the formation of a much greater quantity of pus than was brought there by the blood.

The mode of formation of these abscesses is well illustrated by an experiment made by Dr. Saunders, and related by him, exactly half a century ago, in his Gulstonian lectures in this place.

He injected ʒij. of quicksilver into the crural vein of a dog. No ill effects were observed the first day; but at the end of this the dog became feverish, and after two or three days had cough and difficulty of breathing, which continued until its death. On examination after death, Dr. Saunders

found the lungs studded with small indurated masses, which he calls tubercles, and small circumscribed abscesses. In the centre of each was a small globule of mercury.

Here, the globules of mercury, like the globules of pus in purulent phlebitis, became arrested in the capillary vessels of the lungs, and each globule, acting, perhaps, by mere mechanical irritation, excited circumscribed inflammation and abscess. The inflammation was circumscribed, because the irritation that excited it acted only at particular points.

In the dog experimented on by Dr. Saunders, the lungs were the only organs in which abscesses were found. The reason of this is obvious: all the mercury, conveyed directly to the lungs, became arrested in their capillaries. No globules passed through to cause inflammation and abscess of other organs.

In the same way, in some cases of purulent phlebitis, abscesses are found in the lungs only; and they are usually found in the lungs in greater number than in other internal organs. After the lungs, the liver is the organ in which they are most frequent—a circumstance to be attributed to the large size of the liver, to the great quantity of blood that flows to it, and perhaps still more to the slowness of the current through its capillary network.

In the liver the abscesses are often scattered, as in the lungs; but they are usually larger, and less regular in their outline, than in the latter organ—a consequence, it would seem, of the anatomical fact noticed by Mr. Bowman, that the lobules of the liver are not distinct bodies, separated from each other by a layer of cellular tissue, but that their capillaries form a continuous network throughout the entire organ.

For a long time it was strongly objected to the doctrine, that the disseminated abscesses consequent on injuries and operations are formed in the way here supposed, that in many such cases no inflamed vein can be found after death.

This objection was much weakened by the important observation made by Mr. Arnott, that the effects of purulent phlebitis are not in relation to the size of the vein, or to the extent of the portion inflamed; and that even in cases rapidly fatal the portion of vein inflamed is often very small. Mr. Arnott infers, and no doubt justly, that in many cases we fail to discover the source of the mischief on account of the small size of the vein or the small portion of it inflamed.

Another important observation has been made by Cruveilhier, which goes far to complete our knowledge of phlebitis, and almost entirely removes the objection I have stated: it is, that after operations or injuries where a bone has been divided or broken, the portion of vein inflamed, the source of the

subsequent mischief, is often within the bone. He maintains that operations and injuries that involve bones are those most frequently followed by disseminated abscesses; and that inflammation of the veins in the interior of bones is more apt to cause them than inflammation of the veins of other textures.

He accounts for this by the circumstance that the vascular canals of bone cannot collapse like the vessels of other textures; and further supports his opinion by the following experiments:—

He removed the marrow from the thigh-bone of a dog, and put mercury in its place. At the end of four or five days the dog died, and the mercury was found disseminated through the lungs. Each globule was the centre of a small hepatised mass (*foyer d'inflammation*.)

In another dog he placed a single globule of mercury in the medullary cavity of the femur, and a month afterwards found it in the lungs, divided into many very small globules, each the centre of a small abscess.

The observation of Cruveilhier, that injuries which involve bones are those most frequently followed by disseminated abscesses, embraces, as a particular instance, the fact, long ago noticed, that injuries of the head are often followed by abscesses of the liver.

From the researches of Mr. Arnott, in this country, and of MM. Dance and Cruveilhier, in France, no doubt remains that the abscesses in such cases result from suppurative inflammation of a vein, either in the soft parts, or between the tables of the skull.

Many false theories of the mode of formation of the abscesses of the liver consequent on injuries of the head have been maintained under an erroneous impression, that the abscesses exist in the liver only. It was, however, long ago remarked by Morgagni, that in these cases there are often abscesses in the lungs, heart, spleen, and other organs, as well as in the liver. The abscesses of the liver attracted more attention than those of the lungs, on account, perhaps, of their larger size, and their being more conspicuous, from the stronger contrast between the colour of pus and the natural colour of the organ.

It may be considered, then, established, that the abscesses which form in the liver and other organs, after surgical operations and injuries, are owing to suppurative inflammation of a vein, and the consequent contamination of the blood by pus. The globules of pus, entering the circulation, are conveyed to the capillary vessels of the lungs, and, it would seem, by becoming mechanically arrested there, excite each circumscribed inflammation and abscess. If

any of the globules pass through the capillaries of the lungs to the left side of the heart, they are sent in the arterial current to other organs, and becoming arrested in the capillaries of those organs, excite, as in the lungs, inflammation of limited extent, rapidly passing to abscess.

These disseminated abscesses are most commonly found after operations or injuries, because suppurative inflammation of a vein is most commonly caused by mechanical injury of its coats; but they may obviously result from suppurative phlebitis set up in any other way. I have met with two instances in which disseminated abscesses in various organs seemed to result from a collection of pus that had formed, from some cause which I could not discover, between the periosteum and bone of the upper arm; another instance, in which their source was probably a large tuberculous cavity in the lungs.

Perhaps, then, we are justified in concluding, in all cases in which we find collections of pus rapidly formed in different parts of the system, that the immediate cause of these scattered inflammations is some irritating substance conveyed there by the blood; and, in most of the cases where the abscesses in the lungs are small and circumscribed, that this irritating substance is pus, derived from inflammation of the inner surface of a vein.

The proportion of cases of this kind, in a given number of cases of abscess of the liver, will of course vary with the frequency of abscess of the liver from other causes.

In India, where other powerful causes of abscess of the liver are in operation, the proportion will be small. In the cases published by Annesley, there is not one that we can, from his description, place in this category. In the fifteen cases I observed at the Dreadnought, there is only one that clearly belongs to this head: in this instance, abscess of the liver, with abscesses of the lungs and collections of pus in various joints, resulted from phlebitis caused by the operation of bleeding.

In the fifteen cases collected by Louis and Andral, in Paris, where abscess of the liver from other causes is less frequent, there are four which may be placed in this category:—one, in which the abscesses were consequent on venesection; another, in which they were consequent on childbirth; a third, where, with abscesses of the liver, there was lobular pneumonia of the left lung, grey hepatisation of the right, and pus between the vertebral column and pharynx; a fourth, in which there was grey hepatisation of the lower lobe of the left lung, and pus in the mediastinum.

There is strong analogy between the disseminated abscesses from phlebitis and disseminated masses of cancer.

A cancer of the breast may be the source of cancerous tumors in the lungs and liver, just as an inflamed vein in the arm may be the source of abscesses in those parts.

The abscesses and the secondary cancerous tumors will be scattered in the same manner, and immediately surrounded by healthy pulmonary or hepatic tissue.

The lungs and the liver are the organs in which secondary cancerous tumors, as well as the abscesses from phlebitis, are most numerous.

The cancerous tumors and the abscesses have in each organ the same form and seat; and in the lungs both have a great predilection for the surface.

These points of resemblance depend on the germs of the two diseases—cancer-cells and pus-globules—being disseminated in the same manner through the veins.

I have as yet alluded only to inflammation of a vein that returns its blood immediately to the vena cava, in which case the pus has to traverse the capillaries of the lungs before it can be sent to other organs. In such cases abscesses are sometimes found in the lungs only, and are always more numerous in them than in other organs. But if one of the veins that go to form the vena porta be inflamed, the pus will be carried to the liver first, and abscesses will be found solely, or in greatest number, in that organ.

Cruveilhier found that if mercury be injected into one of the veins that feed the porta, it will be arrested in its course through the liver, and will cause circumscribed abscesses there, just as it does in the lungs when injected into the crural vein.

He injected mercury into one of the mesenteric veins of a dog. At the end of twenty-four hours the dog died, and the surface of the liver was found sprinkled with small spots, of a deep red colour, which extended four or five lines into its substance. In the centre of each of these spots was a small globule of mercury.

In another instance, having met with a dog having an umbilical omental hernia, he seized the opportunity to inject mercury into one of the small veins of the omentum. The dog was killed in the middle of the third month, and the liver found studded with a countless number of what Cruveilhier calls tubercles, in the centre of each of which was a globule of mercury. Some of these tubercles had two distinct layers—the outer albuminous or tuberculous, the inner puriform.

In these two experiments we see the different stages of suppurative inflammation. At first there is a spot of a deep red colour; this passes to suppuration and abscess; and the matter of this abscess, acting as a source of irritation, excites around it inflammation of a different kind, which terminates in an

effusion of albumen or fibrin, and thus forms a cyst for the matter.

The veins that feed the vena porta are little exposed to accidental injury, but some of their branches are divided in operations on the rectum and for strangulated hernia; and, as might have been anticipated, these operations are sometimes followed by abscess of the liver.

Cruveilhier gives a case where abscesses of the liver were immediately consequent on repeated attempts to return a prolapsed rectum. The patient, a man of sixty, had been subject to prolapsus many years. The bowel protruded at the first effort to empty it, but was usually returned without difficulty. When he sought assistance, it had been down twenty-four hours, and was replaced only after repeated and violent attempts, which gave him much pain. The same day the expression of his countenance altered, and his pulse became small and unequal. He soon fell into a state of prostration, with a cold skin, vomiting, hiccough, stupor, but without pain, and died on the fifth day. A great number of small abscesses,—some superficial, others deep-seated,—were found in the liver; the hepatic tissue, for a short distance round each of them, was of a brown slate-colour, and softened.

Dance mentions a case in which abscesses formed rapidly in the liver after an operation for cancer of the rectum, where cauterisation was practised; another, in which they were consequent on a simple operation for fistula; two others, in which they followed the operation for strangulated hernia, where a portion of irreducible omentum suppurated externally.

There can be little doubt that in all these cases the abscesses in the liver were the consequence of phlebitis caused by the operations.

It is an important circumstance, and one to which I shall again have to refer, that in none of the cases do Cruveilhier or Dance speak of abscesses in other organs. It would seem that all the pus furnished by the inflamed veins was arrested in its passage through the liver, and that abscesses formed in that organ only.

3. The consideration of these cases leads us naturally to a third cause—I believe by far the most frequent cause—of abscess of the liver;—I mean ulceration of the large intestine, or, more generally, of the intestines, the stomach, the gall-bladder, or ducts,—parts which return their blood into branches of the portal vein, to be thence transmitted through the capillaries of the liver.

A connexion between abscess of the liver and dysentery has long been noticed; but the two diseases are, I believe, associated far more frequently than is generally imagined.

Of the twenty-nine cases from Annesley, exhibited in the tables, there are twenty-one, or nearly three-fourths, in which there were ulcers, more or less extensive, in the large intestine; and two other cases in which the large intestine was contracted or strictured, in consequence, no doubt, of dysentery at some former period. It is not unlikely that in some of the remaining cases ulceration of the intestine existed, but was not noticed.

Of the fifteen cases which I examined at the Dreadnought, and which are arranged in this table, the state of the intestines was not noticed in two cases. In eight of the remaining thirteen cases there were ulcers in the large intestine, and in one other case two ulcers in the stomach: so that in nine of thirteen cases, or in nearly three-fourths, there were ulcers in the large intestine or stomach. In another of these cases, without any ulceration of the stomach or intestine, there was ulceration of the gall-duct.

In the fifteen cases collected by Andral and Louis, who seem not to have suspected any connexion between abscess of the liver and ulcerated intestine, ulcers are noticed in the large intestine, and in the lower end of the ileum, in two cases; in the lower end of the ileum only in one case; in the stomach in three cases; in the gall-bladder in one case.

In one of the cases in which the stomach was ulcerated, the ulcer communicated with the abscess, which was in the left lobe of the liver. It is fair to conclude, as Andral does, that in this case the ulcer was caused by the abscess opening into the stomach. Excluding this case, there are still six cases out of fifteen in which there were ulcers in some part of the extensive mucous surface that returns its blood to the portal vein.

The fact will appear still stronger, if we recollect that in one of these fifteen cases the abscess in the liver was caused by a blow, and in four others it seemed the consequence of phlebitis; and that in none of these five cases were there any ulcers in the stomach, intestines, or gall-bladder: so that in six out of ten cases, in which the abscesses were not the consequence of a blow or of general phlebitis, there was ulceration of the stomach, the small or large intestine, or the gall-bladder.

It is quite impossible to suppose that this is a mere coincidence of lesions having no relation to each other. In another of these ten cases, the abscess of the liver was obviously consequent on chronic disease of the stomach; and after death the lining membrane of the stomach was found in some parts so softened as to resemble liquid mucus. In this last case, and in the two cases in which there was an ulcer in the stomach, the state of the large intestine is not noticed.

Here, again, I may adduce, as a further support to my position, the analogy of cancer. Cancer of the stomach is frequently followed by disseminated cancerous tumours in the liver, and in no other organ. I might cite numerous instances of this kind from those storehouses of pathology—the Clinique Medicale of Andral, and the Anatomie Pathologique of Cruveilhier. It would seem that cancer-cells, like pus-globules, usually, if not always, become arrested in the liver, and do not pass through to become the germs of cancerous tumours in other organs.

The association of dysentery with abscess of the liver is noticed by most physicians who have treated of these diseases. Dr. Cheyne, speaking of the dysentery of Ireland, says, that in the majority of his dissections the liver was apparently sound, but that in two cases he found abscesses in its substance.

In one or two of the cases of abscess of the liver published by Dr. Abercrombie, there were ulcers in the large intestine. It is remarkable that Dr. Abercrombie should have considered the association of the two diseases accidental. He says, "Dysentery is often accompanied by diseases of neighbouring organs, especially the liver, in which are found, in some cases, abscesses, and in the protracted cases chronic induration. These are to be regarded as accidental combinations, though they may considerably modify the symptoms."

Annesley, much struck with the frequent association of the two diseases, and impressed with the importance of establishing their true relation, confesses his inability to do this. He supposes that in some cases the abscess is consequent on the dysentery; that in others, the dysentery is the mere consequence of the disease of the liver; while in the third order of cases the disease of the liver and that of the large intestine are coeval, or so nearly coeval that it is almost impossible to decide which has priority. And, indeed, in India it must be extremely difficult to discover the relation between the two diseases, in consequence of the great prevalence of other affections of the liver that are not easily distinguished from abscess during the life of the patient.

In the cases that fell under my own care in the Dreadnought, I experienced the same difficulty, and generally found it impossible to tell, from the history of the case, which had priority, the disease of the liver or the dysentery.

In some cases, however, it was impossible to resist the conclusion, that the abscess of the liver was not only consequent on the dysentery, but caused by it.

On the 12th of March, 1838, four men, Brown, Flett, Creer, and Davies, were brought into the Dreadnought from the same vessel, the *Regoon*, in a dreadful state

of dysentery. The *Renown* had just come from Calcutta, and had lost many of her crew from dysentery between Calcutta and the Cape. At the Cape, having but five men before the mast remaining, she shipped seven fresh hands, among whom were Brown, Flett, Davies, and Crere, at that time in perfect health. Some of the original crew continued to suffer from dysentery after leaving the Cape, but these new hands had good health until, between the Western Islands and the Channel, when they had got into cold weather, they were attacked, one after another, with dysentery of the most severe kind. Two of these men died soon after their admission to the *Dreadnought*; the others so far recovered as to leave the hospital.

In the two fatal cases I found the condition of the large intestine exactly the same—from the ileo-cæcal valve to the rectum, the mucous membrane was almost entirely destroyed by sloughing. In one of these cases, the liver contained three small abscesses, not encysted, and evidently quite recent; in the other, the liver, as far as I could judge, was perfectly healthy. Now the primary disease in the two cases was obviously the same, produced by the same cause; and as disease of the liver was only found in one of them, we must infer that it was secondary, the consequence of the dysentery.

Among many cases of dysentery, there may be only one in which abscesses form in the liver, just as among many cases of amputation, or of injury of the head, there may be only one in which abscesses form in the lungs and other organs.

In another case, No. 8 in the table, the patient had dysentery at the Isle of France. The violent symptoms subsided at the end of two months, and he continued his work for four years; until, while on his passage home from the East, diarrhoea recurred, and he became affected, for the first time, with pain in the right side and shoulder. These symptoms had lasted three months, when he was brought into the *Dreadnought*. He died soon afterwards, and on examination I found four large ulcers, three in the lower extremity of the ileum, and one in the cæcum; the neighbouring mesenteric glands much enlarged, and softened to a pulp, of a pinkish colour; and a superficial abscess on the convex surface of the right lobe of the liver. The mucous membrane of the small intestine down to the ulcers, and of the large intestine throughout, below the cæcum, was in all respects healthy.

The march of the disease in this case seemed to be dysentery, which had left a few chronic ulcers in the cæcum and lower end of the large intestine; at the end of four years, recurrence of dysenteric symptoms,

inflammation and abscess of the liver. The abscess of the liver clearly dated from the recurrence of the dysenteric symptoms, when the patient first felt pain referable to the liver. An abscess so superficial could not have existed without manifest symptoms.

If I had time, I might adduce other instances in which the abscesses of the liver were clearly secondary to dysentery. We are then led to the conclusion, admitted by Annesley, that abscess of the liver is in some cases consequent on dysentery, and obviously caused by it.

The question now arises,—is it not so caused in all the cases, or in most of the cases, in which the two diseases are associated?

Annesley thought not, from the circumstance that, in India, the symptoms of liver disease are sometimes coeval with those of dysentery, in other cases prior to them.

The circumstance that the symptoms of liver disease are coeval, or nearly coeval, with those of dysentery, does not prove that the former disease is not dependent on the latter. In the case I have cited from Cruveilhier, in which abscesses in the liver were caused by the rough handling of a prolapsed rectum, the symptoms commenced almost immediately after the injury, and, at the end of five days, when the man died, the matter in the abscesses was fully formed. After an amputation or injury, inflammation of a vein may occur, pass to suppuration, and contaminate the system, in less than forty-eight hours. Supposing, then, the suppurative inflammation of the liver to be excited in the same way in dysentery, we should expect that its symptoms would, in some cases, be almost coeval with those of the primary complaint.

But, in India, it sometimes happens that the symptoms of liver disease precede those of dysentery. This, also, is what might have been expected.

In India, derangements of the liver, consisting in excessive and perhaps vitiated secretion of bile and inflammation of the gall ducts, are very common; the consequence, it would seem, of the heat of the climate, and the free living in which the English in India indulge.

Adhesive inflammation of the liver, terminating in induration and cirrhose, is also very common there, as in this country, from spirit drinking. Now, although neither of these affections may terminate in suppurative inflammation of the liver and abscess, yet they present nearly the same symptoms, and may be readily mistaken for it. If, then, a person with any such derangement of the liver should become affected with dysentery and its consequence, abscess of the liver, it is very natural that the dysentery should be ascribed to pre-existing suppurative inflammation of the liver.

If the explanation I have offered be rejected, we are driven to conclude, as Annesley does, that the dysentery in these last cases is caused by the passage of irritating bile. Now, if this were the case, we should expect to find the most evident marks of disease in the gall-ducts and the upper part of the small intestine—parts with which the irritating secretion came first in contact; but, instead of this, these parts are almost always perfectly healthy in cases in which abscess of the liver is associated with the most destructive forms of dysentery. The whole of the large intestine may be a complete slough, while the gall-bladder and ducts, and the small intestine, almost down, or even quite down, to the ileo-cæcal valve, are perfectly healthy, and the bile in the gall-bladder is of its natural consistence and colour.

There can be no doubt that a copious flow of irritating bile may cause diarrhoea—it may perhaps cause ulceration—but it is very improbable that it causes the early and extensive ulceration and gangrene of the large intestine in Asiatic dysentery, which often destroys life in a few days, while the small intestine almost in its entire length remains perfectly healthy.

The more probable explanation is that which I have before given—that in these cases the patient had some derangement of the functions of the liver, which was followed by dysentery and abscess; and, consequently, that in all the cases, or most of the cases, in which abscess of the liver and dysentery are associated, the former disease is the consequence of the latter.

If irritating bile causes ulceration of the intestine, it may be the remote cause of abscess of the liver, but only through the disorder it first occasions in the intestine.

Admitting dysentery, or ulceration of the bowels, to be a source of abscess of the liver, it is obvious that the liver does not become affected by spreading of the inflammation, but by some contamination of the portal blood.

This may be either by *pus*, formed by suppurative inflammation of one of the small intestinal veins; or by the fetid gaseous and liquid contents of the large intestine in dysentery, which must be absorbed and conveyed immediately to the liver. It is, I think, probable, that contamination of the former kind usually gives rise to small disseminated abscesses; of the latter, to diffuse inflammation, and a larger, perhaps single, collection of *pus*. If the morbid matter be such that it does not mix readily with the blood—as globules of *pus* or mercury—it will cause small circumscribed abscesses, the rest of the liver being healthy. If, on the contrary, the morbid matter be volatile, or readily diffusible in the blood, all the blood will be vitiated, and diffuse inflammation result.

The admission of this explanation of the relation of abscess of the liver to dysentery would lead us to expect that abscess of the liver might occasionally be consequent on ulceration or organic disease of the stomach or gall-bladder—parts which, like the large intestine, return their blood to the portal vein: and this is found to be the case.

I have already remarked, that in the fifteen cases of abscess of the liver recorded by Andral and Louis, there are two in which the stomach was found ulcerated, without any ulceration being noticed in the intestines or gall-bladder.

In the first of these two cases (Obs. 30, Andral), the patient, a man sixty years of age, had presented for a considerable time the symptoms of chronic gastritis—loss of appetite, vomiting, acid eructations, a sense of weight at the epigastrium. He became sallow, and lost strength and flesh. He was somewhat benefitted by milk diet and soothing measures, when, all at once, his pulse became frequent, he fell into a state of prostration, his tongue became brown, and he died at the end of some days.

The coats of the stomach, for the breadth of five or six fingers in front of the pylorus, were much thickened; the mucous membrane was ulcerated; and, in place of the subjacent tissues, there was a uniform gristly substance, of a dead white colour.

There was adhesion, by bands of cellular tissue between the stomach and liver.

The liver was of its usual size. In the left lobe was a cavity, the size of a small apple, filled with *pus*, and lined by a thick and resisting membrane. The hepatic tissue surrounding the abscess was in a state of gangrene.

In this case, the abscess of the liver could not have caused the ulcer of the stomach; but the ulcer may fairly be presumed to have been the cause of the abscess. The abscess was chronic. The state of prostration marked the occurrence of gangrene about it.

In the second case (Obs. 4 of Louis), the patient, a man of fifty, had had for four years disordered digestion, irregular appetite, occasional slight pains in the left hypochondrium, now and then nausea and purging, and often had alternating of leanness and moderate *embonpoint*. Seventeen days before his admission to the Hospital he became much worse than usual, and had a set of new symptoms—heat of skin, jaundice, complete loss of appetite, severe pain at the epigastrium and in the left hypochondrium, and slight oppression. The symptoms continued, and in the last eight days he had, in addition, purging and some nausea. He died a fortnight after his admission.

The liver was somewhat larger than natural, and contained a great number of small abscesses, bounded by a thin and soft false

membrane. Its tissue was softened throughout.

The gall-bladder was small, and obliterated at its neck. The cystic duct contained a gall-stone. The coats of the gall-bladder and cystic duct much indurated and thickened. The hepatic duct, and the ductus communis, perfectly healthy.

In the portion of the stomach intermediate to the splenic and pyloric extremities, the mucous membrane was thicker than natural, and presented many deep ulcers, three or four lines in breadth.

Here, as in the former case, we cannot ascribe the ulcers in the stomach to the disease of the liver, but the abscesses in the liver may be fairly attributed to the disease of the stomach. There was likewise, indeed, disease of the gall-bladder and cystic duct, but this, which was of long standing, presented no marks of recent activity, whereas it was obvious that the abscesses in the liver were of recent date.

In another case given by Andral, to which I have already alluded, an abscess of the liver seemed consequent on softening of the mucous membrane of the stomach. The patient, a man aged 51, had symptoms of chronic gastritis for 18 months, when he became jaundiced, and began to have a constant and troublesome pain in the right shoulder. After the accession of these last symptoms,—Andral does not say how long,—he was seized suddenly with symptoms of peritonitis, and died at the end of three days.

In the liver was an abscess, not encysted, which had opened into the cavity of the peritoneum on the under surface of the liver, near the gall-bladder. The gall-bladder and ducts were healthy. In the splenic extremity of the stomach, the mucous membrane was much softened, in some parts so much as to resemble liquid mucus on the subjacent tissue. In the pyloric extremities of the stomach, on the contrary, the mucous membrane was hypertrophied.

Here, symptoms of disease of the stomach had lasted 18 months before the patient had any symptoms of disease of the liver. The circumstance that the abscess was not encysted tends to prove that it was of recent date.

Ulceration of the gall-bladder or ducts seems equally efficient with ulceration of the stomach in causing abscess of the liver.

I would instance as a probable example of this, the last case given by M. Louis (Obs. 5, Louis). The liver contained from 30 to 40 abscesses, from the size of a pea to that of a filbert, not encysted, and evidently of recent date.

There was no ulceration of the stomach or intestines, but in the gall-bladder, which contained some small calculi, there were six round ulcers, three superficial and three

deep. The mucous membrane of the gall-bladder was tripled in thickness.

A case very similar to this is given by Dr. Bright, in the first volume of Guy's Hospital Reports :—gall-stones, ulceration of the gall-bladder, numerous abscesses in the liver.

With these cases may be classed one of the cases I had to treat at the Dreadnought.

The patient, aged 33, was brought into the hospital on the 2d of December, immediately on his return from Quebec. At Quebec he had ague, and this was succeeded, three weeks before his admission, by jaundice and pain below the ensiform cartilage. He was given, first salines, then quinine, then iron. The jaundice continued, but he had gained strength, when, on the 26th of January, just eight weeks after he was brought into the hospital, he was seized suddenly with symptoms of peritonitis, which carried him off in four days.

On the convex surface of the right lobe of the liver was a large irregular abscess, lined by a yellow, buffy, false membrane. The gall-bladder, whose cavity was no larger than a hazel-nut, was filled by a yellow, ochery, matter, surrounding a firm dark-green nucleus. It was firmly adherent to the duodenum, and its coats were thickened. The cystic duct was much dilated, and contained a similar calculus, the size of a small bean. The common duct was nearly as large as my little finger, and communicated with the duodenum by an ulceration rather larger than a split pea, about two or three lines from the natural termination of the duct, which was very obvious as a papilla. The hepatic ducts were very large, and were readily traced a long distance into the liver.

There was no ulceration of the stomach, or of the intestines, with the exception of this ulcerated opening in the duodenum.

In the 29 cases from Annesley, which I have exhibited in the tables, there are, as I have already remarked, 23 in which there were ulcers, or the cicatrices of ulcers, in the large intestines. In 4 only of these 23 cases does Annesley notice any morbid change in the gall-ducts; while he remarks it in 3 of the remaining 6 cases.

In 1 of these 3 cases, (case 81) the gall-bladder was very small, and seemed to be divided by a stricture in the centre.

In another, (case 93) the common duct was much compressed and obstructed by enlargement and hardening of the pancreas, which completely enveloped it. On laying the ducts open, there was found at the mouth of the gall bladder a considerable thickening and cartilaginous band constricting this part. The intestines, small and large, were sound, both internally and externally.

In the 3d case, (case 126) the gall-bladder completely adhered to the walls of the abscess, and communicated with it. The

ducts were impervious, being involved in the adhesive inflammation of the parts forming the parietes of the abscess; and the bile secreted by the liver was either retained in the abscess, or discharged by the wound. (The abscess had been opened). There was no other appearance of disease in any of the viscera.

The ducts, the gall-bladder, and the capsule of the liver, are nourished by the hepatic artery, and blood flows, not from the portal vein to them, but from them to the portal vein. This circumstance explains how ulceration of the gall-bladder, like that of the stomach or intestines, may cause abscess of the liver; and it also explains the fact, noticed by most men who have seen much of abscess of the liver, that in this disease the gall-bladder, ducts, and capsule, are rarely affected. The suppurative inflammation is confined to those parts of the liver that receive blood from the portal vein. The frequent absence of any trace of inflammation of the capsule in cases of abscess of the liver has been expressly noticed by Annesley and by Dr. Stokes as very important in reference to treatment.

Having collected instances of abscess of the liver apparently originating in a vitiated state of the blood brought from the mucous surfaces that feed the portal vein, we require, to complete our catalogue of abscesses of the liver produced by contamination of the portal blood, instances in which the contaminating matter is brought by the splenic vein. My friend, Mr. Busk, has furnished me with notes of the appearances after death in a case which seems to have been of this kind.

The liver contained a great number of abscesses, about the size of walnuts, containing thick white pus. The intermediate hepatic substance did not seem inflamed. It was pale, firm, and of natural appearance.

The splenic vein was much dilated. The branches by which it arises from the spleen, and all that part of it which runs on the pancreas, were inflamed, and contained a puriform fluid and an irregular deposit of lymph.

A large portion of the spleen was pale, and partially separated by a gangrenous mass from the rest of the organ, which was of a deep red colour and very soft.

There were no ulcers in the intestines; no abscesses anywhere but in the liver.

The most probable supposition is, that the disease in this case originated in the spleen; that the splenic vein subsequently became inflamed, and that the disseminated abscesses in the liver were caused by the noxious matter brought to it by the vein. If this matter were pus, we have another instance of pus brought in large quantity to the portal vein being all arrested in its passage through the liver.

A circumstance that cannot fail to have struck you as strongly confirmatory of the view I have taken of the different sources of abscess of the liver in the cases I have brought before you, is, that you do not find more than one of these probable sources in the same subject. Where the abscess could be traced to a blow, or to suppurative inflammation of some vein that returns its blood immediately to the vena cava, there were no ulcers in the stomach, intestines, gall-bladder, or ducts. When ulcers were found in the intestines by which the occurrence of abscess in the liver could be explained, there were no ulcers in the stomach or gall-bladder. When the stomach was ulcerated, there were no ulcers in the intestines, or in the passages of the bile. When there were ulcers in the gall-bladder or ducts, there were none in any part of the intestinal canal.

It is not, however, every form of ulceration of the stomach and intestine that gives rise to abscess of the liver. I have never seen abscess of the liver noticed in conjunction with simple ulcer of the stomach, or with ulcerated intestine in typhoid fever. This last fact is very striking, when we consider how prevalent and fatal typhoid fever is, how generally it is attended with extensive ulceration of the bowels, and how attentively all the morbid appearances in this disease have been observed and recorded of late years, in this country and in France.

Abscess of the liver is not noticed in any of the cases (ten in number) of ulceration of the duodenum after burns, given by Mr. Curling in his paper in the *Medical and Chirurgical Transactions* for 1842.

It is very rare in conjunction with ulceration of the intestine, in phthisis. In two of the cases given by Andral in which abscess of the liver was associated with ulceration of the intestines, there were tubercles in the lungs, and the ulcers were probably of tuberculous origin. But these form an insignificant proportion in the immense number of fatal cases of phthisis with ulcerated intestines, in which the morbid appearances have been observed and recorded.

Abscess of the liver seems to occur chiefly in conjunction with the sloughing ulceration in acute dysentery; and with chronic ulcers attended with thickening and induration of the submucous cellular tissue. In the latter cases, the inflammation of the liver occurs on some exacerbation of the gastric or dysenteric symptoms.

The explanation I have given of the mode of production of abscesses of the liver associated with dysentery, applies to a large proportion of the cases not attributable to the causes I have previously noticed; blows on the side, and suppurative phlebitis. There remain, therefore, but few cases that

require us to admit the agency of other causes.

Yet various other influences are very confidently assigned as causes of suppurative hepatitis. Among these I may mention—

1. Inflammation of the duodenum.

Great importance was attached to this cause by Broussais and his followers. Broussais, having noticed that the lymphatic glands in the vicinity of ulcerated mucous membranes are often enlarged and inflamed, and dwelling on the known sympathy between some secreting glands—the lachrymal, the salivary—and the adjacent mucous membranes, was led to generalise, and to assign inflammation of the duodenum as the most frequent cause, indeed as almost the only cause, of inflammation of the liver. This opinion is not borne out by facts. In the tables exhibiting the cases collected by Andral and Louis, and those observed by myself, the condition of the duodenum is noticed in a separate column. In hardly one did it present any trace of disease. Ulceration or organic disease of the duodenum may cause abscess of the liver, like similar disease of other parts which transmit their blood to the portal vein, but such disease is very rare in the duodenum.

2. Another cause assigned for hepatitis is the drinking freely of spirits. But this produces adhesive inflammation and induration of the liver, not suppurative inflammation and abscess. Notwithstanding the habit of gin-drinking by the lower orders in this metropolis, years often pass away without a single case of abscess of the liver being admitted into a large London hospital. Not one has been received into King's College Hospital since its establishment.

3. A third cause confidently assigned by Annesley, and many other writers, is congestion of the liver; but this, assuredly—that is, mechanical congestion—never produces suppurative inflammation. We never meet with abscesses of the liver as a consequence of the congestion caused by the organic diseases of the heart so common in our hospitals; and in not one of the cases exhibited in the tables could the abscesses be attributed to this cause.

4. In India great influence is attributed to the heat of the climate as a cause of inflammation and abscess of the liver. A high temperature, no doubt, deranges the functions of the liver, and causes increased secretion of bile and inflammation of the gall-ducts. It may perhaps also directly cause suppurative inflammation and abscess; but I feel persuaded that it does so far less frequently than is generally imagined, and that the notion originated from the prevalence of *dysentery*, the most frequent cause of abscess, in many tropical climates. The heat of our own summers, or of those of France, never

brings on abscess of the liver, which is very rare in the civil hospitals of London and Paris. Sailors employed in the trade to the west coast of Africa are exposed to heat just as great as those in the trade to India, and suffer much more in health, but they are not equally liable to abscess of the liver.

Men employed in japanning, and other processes of the arts, are often exposed, and for a considerable time, to heat much greater than that of India, and their health suffers in consequence, yet we never find them coming into our hospitals with abscess of the liver.

5. Another cause brought forward to explain the frequency of abscess of the liver in India is remittent and intermittent fever; but I believe this has no influence except by producing ulceration of the bowels.

During the time I was visiting physician to the Dreadnought, I had continually to treat men in the most deplorable condition from fever caught on the coast of Africa, but none of these men had abscess of the liver.

Dr. McWilliam, the chief surgeon to the late unfortunate Niger expedition, tells me that he did not find abscess of the liver in any of the examinations he made (they were very few in number) of the victims of the malarious fever of the climate.

Louis, in his elaborate account of the yellow fever, which he was sent by the French government to observe at Gibraltar in 1828, says he constantly found the liver of a pale slate colour from anemia, but presenting no marks of inflammation.

Annesley, indeed, notices abscesses in the liver among the morbid appearances of the remittent fever of India, but he also notices ulceration of the intestine. Sir Gilbert Blane, in his account of the Walcheren fever, remarks that the liver was occasionally the seat of abscess; but here, as in India, the fever was associated with dysentery. It is, I think, fair to conclude that, in both cases, the abscesses in the liver were the consequence of the dysentery, and not the immediate effects of the fever.

MR. LEE ON BELGIAN MEDICAL INSTITUTIONS.

(For the *London Medical Gazette*.)

Ghent.—The building of the university is one of the finest of the kind in Europe. Its handsome façade, lofty portico, spacious circular vestibule, with marble staircase on either side, will not fail to strike the visitor. The amphitheatre for examinations and promotions, capable of containing nearly 1000 spectators, with its stuccoed

columns, royal box, and tasty fittings-up, presents a rich appearance, and is occasionally used for other than university purposes. Each faculty has its separate class lecture-rooms on the ground floor, all the lectures being delivered by the professors within the building. There is a museum of natural history, and a cabinet of pathological anatomy, which, however, is but indifferently furnished, and contains nothing remarkable.

The number of students is about 500, of which one-third attend the medical classes. The following are professors in the Faculty of Medicine:—Dean, and Professor of Descriptive and Pathological Anatomy, M. A. Burgræve. Human and Comparative Physiology, Guislain. Pathology and Therapeutics, Van Coetseur and De Block. Pharmacy and *Materia Medica*, Hensmans. Surgical Pathology and Clinique, Verbeeck. Obstetrics, Hondet. Ophthalmology, Roosbroeck. Medical Jurisprudence, De Block. Surgical Clinique, Kluyskens. Medical Clinique, Van Coetsan. There are also special courses of lectures on diseases of the skin, bandages, and instruments, &c. delivered by extraordinary professors and *agregés*.

The civil hospital is an ancient building, having the appearance of an unfinished church, of which the lofty roof, supported by bare rafters, presents a comfortless aspect; walls, about eight feet high, extending the whole length, form a central passage, on either side of which the beds are ranged in triple rows—the men on one side, the women on the other; the clinical cases being placed in the centre row. The whole number of beds is about 300; they are of iron, without curtains. The surgical wards are at the end, in the chapel, and contain about fifty beds each. At the time of my visit, the professor was absent, and there were no cases of particular interest. The most frequent disease admitted into the medical department are phthisis, bronchial inflammation, diseases of the heart, gastro-enteric irritation, and diseases of the kidneys, which are very prevalent in many parts of Belgium. Among the patients was a female, of about 22 years of age, who, in consequence of an attempt at rape, had lost the use of her lower extremities, and had not had any evacuation of the bowels for four

months, notwithstanding active medicines, as croton oil, had been given, as also two ounces of crude quicksilver. Neither had she taken any nourishment for more than three weeks. When anything was introduced into the stomach, it produced vomiting. There likewise seemed to be a total cessation of the secretion of urine, as, though closely observed, she was never observed to pass any, the utensil being always empty; and on the introduction of a catheter but a very small quantity was evacuated. She laboured under constant hiccup. The patient was of an obtuse appearance, and the practitioner, who brought her into the hospital in order that the case might be more closely watched, had no reason to suspect any deception, against which he had taken all possible precaution.

Surgical operations are not of frequent occurrence; stone is very rarely met with; and diseases of the eyes are much less frequent at Ghent than at Brussels. Sentin's method of treating fractures is only employed in some cases. The syphilitic wards contain twenty beds. The solution of Van Swieten, and the proto-ioduret of mercury, are the remedies mostly had recourse to in these cases.

Adjoining the civil hospital is the *Hospice de la Maternité*.

The institution for the insane, consisting of two compartments, at a distance the one from the other, contains about 400 patients. Its organization has been greatly ameliorated within the last few years, under the superintendence of M. Guislain, so that it may now rank among the first of these institutions upon the Continent. The women's department is built round three court-yards, planted with trees; the gallery on the first floor, upon which many of the rooms open, overlooking the court, is guarded by wooden railing, extending to the roof, so that the patients may walk about without danger. Each of these rooms contains three beds. Many of the patients, however, sleep in wards containing from twelve to twenty beds. About 150 assemble at dinner, the greatest order prevailing. After a prayer, and during the repast, passages are read from instructive books by a sister of charity. The number of these sisters is eighteen, and to their soothing influences may be ascribed much of the tran-

quillity and order that reigns. The majority of the patients are separated from the turbulent, or those dirty in their persons, but there are no separate divisions according to the nature of the insanity. All are clothed in dresses belonging to the establishment, which, however, are not of a uniform colour. The most common means of repression are the *camisole*, and a belt passing round the body enclosing the arms, but leaving the hands free. The paralytic, and dirty patients, are confined on a chair (the latter on a *chaise percée*,) during the great part of the day, the hands resting on a wooden case. There are two or three work-rooms where several of the patients are occupied. Some convenient cells on the ground floor have been latterly constructed for the unruly, by the direction of M. Guislain. The look-out is upon the garden. Each cell has a clean bed, and two or three necessary articles of furniture; a window furnished with iron bars, and a door opening into a vestibule from which the air in cold weather is excluded by half-glass doors, so that the patient can see what is going on outside. In the vestibule is a stove in winter, and a bed for the superintendents. Some patients, above indigence, contribute partly to their support; there is likewise a separate division for about thirty patients of the superior order of society. Each room is clean, neatly, some even handsomely furnished, and there is a pretty garden for out-door exercise. The payment averages from six to eight hundred or a thousand francs annually. Some, however, pay double this sum, for which they have superior accommodation and attendance.

Mental alienation is not so prevalent among the higher ranks in Belgium as in France. During the political disturbances here as elsewhere the number of insane was greatly increased. The most common causes are domestic chagrin, losses, and other painful moral influences.

The department for the male sex is not so well organised as the female; the locale does not present the same advantages, and there is a comparative deficiency of space for exercise. In the treatment of maniacal exaltation, M. Guislain employs tepid baths, but rarely the douche, sedative remedies, or the abstraction of blood. He speaks

highly of the effect of nauseants; as, antimony, and the sulphate of copper in half-grain doses, in some cases. He has also derived advantage in a few instances from the application of the actual cautery to the nape, which in one case entirely removed the maniacal excitement. It was likewise productive of benefit in a case of epilepsy.

The following is a *resumé* of M. Guislain's opinions upon mental diseases, as given in his work (*Traité sur les Phrenopathies*).

"Abstraction being made of those alterations resulting from mechanical lesion, congenital defect, or which present themselves in the course of acute diseases, the doctrine of mental diseases may be defined in the following manner.

"Almost unknown among nations in a primitive state, and savages, mental alienation shews itself and is multiplied in the very centre of civilization, where constantly succeeding desires and wants are continually in opposition with, and shocking each other.

"An anomaly of the social link which renders existence agreeable, and often at the same time painful to us, it has in the great majority of cases its source in the agencies which interfere with our moral happiness or our interests; sometimes in an intellectual impressionability; an idiosyncrasy transmitted by parents; more rarely in organic defects of the brain; in disorders of the thoracic or abdominal viscera; in morbid alterations of the cutaneous system; occasionally in debilitating causes, and deleterious substances, placed in contact with our textures.

"An affection which, when not arising from a congenital defect of organization, announces a lesion of the affective sensibility, first expressed by a feeling of affliction of melancholy, to which often succeed efforts of repulsion in the instinctive and perfectible qualities, characterised by irregular acts of the will, and vagaries of the imagination.

"A disease of which the primitive character frequently preserves the condition of individuality; sometimes presenting itself associated with phenomena of intellectual reaction or exhaustion, or concealed in some cases, on the appearance of these phenomena, and often presenting itself afresh at the period of convalescence.

"A periodical affection in a great number of cases, generally intermitting at the commencement, passing into the continued remittent state: again acquiring, during its declining period, the remittent, intermittent, or periodical type.

"A chronic disease which, in the greatest number of cases, terminates either in a return to the normal state, or by a diminution in the functional expression of the brain, depending or not upon an organic and secondary alteration of this viscus; the most constant seat of which alteration is in the excentric, lateral, and superior regions of the cerebral hemispheres: an affection giving rise to sympathetic lesions of other organs, especially those of respiration and digestion.

"Mental alienation belongs to the class of the painful neuroses: primitively it is a phrenalgia.

"We have described the different forms under which mental disorders (*souffrances du moral*) appear, by the generic name phrenopathies."

Thus it will be seen that M. Guislain, together with Esquirol, and others who have had extensive experience upon the subject, considers mental alienation as not depending, in the majority of instances, upon any organic or physical change of texture, with which it is not unfrequently accidentally complicated, or which arises as a consequence. This view is further corroborated by the success of the moral treatment in a large proportion of cases, as exemplified of late in several establishments.

PRACTICAL OBSERVATIONS, WITH ILLUSTRATIVE CASES, ON THE

THERAPEUTIC PROPERTIES OF SEVERAL MEDICINES.

BY DR. HUNTER LANE, F.L.S. F.S.S.A.

Corresponding Member of the Calcutta Medical and Physical Society, Physician to the Lancaster Infirmary, &c. &c.

(For the London Medical Gazette.)

[Continued from p. 16.]

THE EXTRACT OF MONESIA.

MONESIA is imported from South America into France. It is obtained as a crude extract from the bark of a tree supposed to be a *chrysophyllum*. Several preparations have been made from this

vegetable substance, but that which I have used is the aqueous extract prepared by MM. Pelletier and Barthémy. It is of a deep brownish-red colour, very friable, and perfectly soluble in water: its taste is, at first, sweet, and then astringent, leaving a permanent impression on the fauces. In doses of from five to eight grains, three or four times a day, I have never known it produce any unpleasant symptoms, or at all irritate the stomach. Its medicinal properties appear to me to be very analogous to those of catechu or kino, nor have I discovered it to possess any conspicuous superiority over those two pharmacopœial preparations. The cases in which I have prescribed it have been different kinds of diarrhœa. In them it has never failed to exercise an agreeable, safe, and uniform astringency over the intestinal exhalants. When administered in cases where there was leucorrhœa coexistent with diarrhœa, it has not appeared to exert any influence over the former complaint, though the latter was obedient to its action.

My exhibition of this extract has been exclusively confined to its internal use, though it is said that the form of injection has been found the most advantageous mode of administering it in vaginal and uterine diseases.

CASE I.—Mr. B—, æt. 30; robust, of a healthy look and choleric temperament, consulted me on the 25th of March, 1843. He was suffering from chronic bronchitis attended with diarrhœa. To the latter complaint he had been more or less liable for three months, but had been much distressed during the last ten days by its aggravation.

R. Misturæ Cascarillæ Comp. ℥iv.; Decocti Scoparii Comp. ℥v.; Spiritus Juniperi Comp. ℥ss.; Potassæ Acetatis, ℥ss.; Extractæ Monesiae, ℥ij. M. capiat coch. ij. majora ter de die. Vesicatorium sterno admovendum.

April 12th.—He felt himself so much improved, his bowels being regular and his cough greatly relieved, that he considered it unnecessary to take any more medicine.

CASE II.—Isabella Wilson, æt. 30, a light complexioned, delicately formed, scrofulous looking woman, became my patient at the hospital on the 18th of March last. She was consumptive, with

considerable excavations in the upper and posterior part of the right lung. According to her own calculation she was about five months advanced in pregnancy. She had had diarrhœa for three or four months past, and it was a relief from this complaint which she sought.

The following mixture was ordered—

R Mist. Cascarillæ Comp. ℥iv.; Infusi Digitalis, ℥ij.; Træ. Gentianæ Comp. ℥j.; Extracti Monesiæ, ℥ij. M. capiat coch. duo majora ter de die.

March 20th.—The looseness completely arrested.

In usu mixturæ perstet.

She did not return to report herself; therefore it is presumed that she had no recurrence of the diarrhœa.

CASE III.—T. H—, Esq. whose case has been adduced in evidence of the unsatisfactory benefit (Case IV.) derived from the administration of mattico in diarrhœa, began on the 8th of April last to take the subjoined mixture.

R Extracti Monesiæ, ℥j.; Infusi Caryophylli, ℥xss.; Træ. Gentianæ Comp. ℥ss.; Confect. Aromaticæ, ℥ss. M. capiat coch. ij. majora ter de die.

On the 30th of April, he wrote thus:—"Your last prescription, containing the extract of monesia, has been decidedly beneficial. I continued it with your dietetic directions for ten days, when I found my bowels in such a satisfactory state, that I gave up taking it. If any relapse takes place I will have recourse to the same mixture again." When I saw him in August last, he told me that his bowels were quite natural. The quantity taken by this patient altogether was two drachms.

CASE IV.—Miss H. Preston, æt. 32, of a dark complexion, delicate figure, melancholic temperament, and unhealthy look, consulted me on the 6th of April, 1843. She had had diarrhœa with varied intermissions for twelve months. She had been treated by alterative and absorbent medicine with occasional, but no permanent relief. The following pills, with injunctions to pay strict attention to diet and exercise, were prescribed.

R Fellis Bovis Inspissati, ℥ss.; Extracti Monesiæ, ℥ss.; Creasoti, ℥iv. M. ut fiant massa in pilulas, xxiv. divid. quarum, ij. ter de die capiendæ.

A week's perseverance in this treatment was attended by considerable improvement in the state of the bowels. By the expiration of a fortnight she was quite well.

CASE V.—Mary Harrison, æt. 37, a debilitated delicate looking woman, of a melancholic temperament, scrofulous diathesis, and hysteric disposition, came under my care on the 3d of April last. She was then suckling a child of 22 months old, and was labouring under the effects of this protracted lactation; leucorrhœa and diarrhœa being the most distressing symptoms. Her bowels were frequently relaxed during the day, and had been in that state for some months. She was directed to wean her child, to improve her diet, and to take the following mixture.

R Decocti Aloes Comp. ℥ij.; Infus. Valerianæ, ℥iv.; Træ. Valerianæ Ammon. ℥v.; Træ. Cantharidis, ℥j.; Træ. Secalis Cornuti, ℥j.; Extracti Monesiæ, ℥ij. M. capiat coch. duo majora ter de die.

April 10th.—No appreciable improvement.

Misturam Ammonio Tartr. Ferri, ℥j. adde.

20th.—The bowels were regular; but no diminution of the leucorrhœa.

CASE VI.—Mrs. W—, æt. 37, a dark haired, sallow complexioned, bilious looking female, of a melancholic temperament and inactive habits, consulted me on the 27th of April, 1843. She had had diarrhœa for a week previously, but during the last two days had been much indisposed by somewhat of a dysenteric affection. For a considerable period she had suffered from leucorrhœa. She had taken no medicines except a dose of castor oil.

With the exclusive use of ox tail or gravy soups as a diet, the following mixture was prescribed—

R Extracti Monesiæ, ℥j.; Infusi Caryophylli, ℥viiss.; Spiritus Myristicæ, ℥ss. M. capiat coch. ij. majora ter de die.

May 2d.—Her bowels were much alleviated; but still the bowels were unnaturally frequent.

8th.—The diarrhœa had entirely subsided; the leucorrhœa had suffered no diminution.

[To be continued.]

REMOVAL OF
DROPSICAL OVARIA, ENTIRE,
BY THE LARGE ABDOMINAL SECTION.

By D. HENRY WALNE, Esq.

(*For the London Medical Gazette.*)

THIRD CASE.

On the 27th of June, 1843, a young lady from the country, accompanied by her mother, called on me, bringing a note from Dr. John Elliotson, whom she had that morning consulted respecting an abdominal enlargement, which had for some time past been a source of anxiety to herself and her friends. Dr. Elliotson having ascertained the presence of dropsical disease of one of the ovaries, and the result of his extensive experience being a conviction of the inefficacy of medicine in the treatment of that malady, had "at once told her not to be tapped, nor to take medicine likely to weaken or even annoy her," and advised her to put herself under my care, if I were willing to operate upon her. Being well acquainted with my "success in operating on the ovarium," he seems to have "regarded it as a duty" to advise her to become my patient, provided neither she nor I objected to the operation. Having perused the note, not without some admiration of the manly frankness by which it was characterized, I proceeded to investigate the case of Miss A. K., who had not quite completed her twentieth year.

More than four years ago it had been observed that she was larger in her person than was natural; so much so, that the mistress of the school at which she was then a pupil had written to her mother, intimating that something was wrong in her state which gave her a very matronly appearance. She herself is of opinion that at a much earlier date she had been unnaturally large, and believes that her complaint originated in an attack of inflammation, for which leeches had to be applied to the abdomen, when about eleven years of age.

Having left school at Midsummer, 1839, she became a governess in a private family; but towards the end of the year her size excited so much observation, and caused so many unpleasant remarks on the part of persons who did not know it to be the effect of dis-

ease, that she was obliged to return home. A professional opinion was in consequence taken, and she was pronounced to have ovarian dropsy.

From the time at which the nature of her case became known she underwent various courses of medical treatment prescribed by experienced practitioners. Mercurial alteratives, repeated emetics, an ointment rubbed upon the skin of the abdomen till it produced an appearance like erysipelas, and a variety of other remedies, were duly tried, but her size continued to increase gradually, no benefit whatever being derived from any of the means employed. For six months before she applied to Dr. Elliotson, with the exception of a short trial of garlic in gin, and broom tea, which some friends recommended, and which were of no service, all medicines had been discontinued.

She began to menstruate in her 14th year, was quite regular in that respect from the first, and always continued so, never experiencing any material suffering or inconvenience on those occasions. At about fifteen she went through a fever, but was never again affected by abdominal inflammation from the time of the illness which occurred when she was not more than eleven years old.

On examination I found the abdomen as prominent as at the full period of pregnancy, with greater fulness towards the loins. The tumefaction was circumscribed, very regular, and distinctly fluctuating; the health in all respects good; not the slightest sign of general dropsy present, and the uterus perfectly natural. I could find no circumstance to create a suspicion of the existence of adhesions; and she had never been tapped. Though of a tall, rather slim general figure, and thin in person, she measured forty inches in circumference.

Having informed Dr. Elliotson that I considered the case suitable for operation, but that, before arranging for its performance, if the patient and her friends agreed to have it done, I should wish Dr. Blundell's opinion should be taken, and this proposition receiving his approval, the result of our conference was declared. The young lady herself was very prompt in decision, being determined to submit to any operation rather than continue the

subject of such annoyances as her disease occasioned. Her friends were more deliberate, and received much contradictory advice. In August the matter was so far settled that Dr. Blundell was consulted, and his opinion, after careful investigation, found to be favourable. By this time also I perceived that, from whatever cause, she was sensibly losing flesh, whilst her complaint was as evidently gaining ground. Three-quarters of an inch additional abdominal circumference, with a thinner state of her general person, were plain intimations of the advance of mischief; and already her size was such as indicated a diseased ovary of much greater magnitude than had been met with in either of my previous operations. I therefore drew attention to these circumstances, and suggested that further delay would add to the hazard of the operation.

On the 29th of August she took up her abode in excellent quarters, with a prospect of the best nursing, and the most kindly discreet management of every thing relating to the coming occasion. Her menstruation had continued to be quite regular up to this time, and her last period had concluded on Friday the 18th.

It was my purpose to operate on Friday the 1st of September. In the meantime she was subjected to similar preparation as my two former patients, viz. abstinence from meat, and wine or other stimulating beverage. She also took aperient medicine of a mild description several times; but being young, and, as I conceived, on that account more likely to be the subject of inflammatory attack after the operation, I thought it prudent to take eight ounces of blood from her arm on the day previous to the one fixed for its performance. She bore the bleeding well, not being at all faint. Once, indeed, some hours after, she felt a slight giddiness. Two nights in succession she had taken, as her bowels were not very freely moved by the first dose, the following pills.

R Ext. Colocynth. c. grs. viii.; Hyoscyam., grs. v.; Pulv. Antim. grs. ij. M. et div. in pil. iij. h. s. sumend.

To-day, August 31, they had operated thrice copiously.

They were directed again, omitting the antimony. Her buoyant animation and activity were scarcely repressible

by these means, by injunctions of quiet or the expectation of the operation.

Sept. 1st.—It was intended that the operation should be performed to-day, and the skin of the abdomen was marked last evening for the purpose. At 1 p.m. I saw her, and she was quite prepared in mind, and apparently in an excellent state of bodily health for the occasion; moderately lowered in tone, but with a calm soft pulse of about 80. The action of the pills had been attended by a little griping; and, soon after I left the house, she remarked to the nurse that she felt as if she were about to be unwell. Between this and three o'clock the catamenia appeared, and I consequently postponed the operation, but was not aware of the circumstance soon enough to prevent my friends arriving one after another to their appointment at four.

Having gone through her customary period of from three to four days, she was again well on the 5th of September, but the operation was not fixed for an earlier day than the 12th, that the tendency to relapse in this matter might be completely at an end. Her diet was very moderate during the whole of this time in respect to animal food, and for the last five or six days this was strictly forbidden. The following draught was taken on the morning of the 10th.

R Pulv. Rhei, ʒj.; Potass. Tart., Mannæ, aa. ʒj.; Spir. Ammon. Ar. ℥xv.; Tr. Hyoscyam. ℥xx.; Tr. Sennæ, ʒj.; Aq. Piment. ʒxj. M. ft. haust.

It operated well. On the evening of the eleventh, I found her in all respects in a desirable state for the operation. Menstruation had ceased about a week, and no threatening of a return had been felt.

R Extr. Colocynth. c. grs. viij.; Hyoscyam. grs. v.; M. et div. in pil. iij. h. s. s.

These did their duty effectually next morning.

12th.—I visited my patient about mid-day, and though hardly required, a little refreshed the marks upon the abdominal skin. The weather was hot, but the chill of instinctive apprehension had given her a cold hand and a pale cheek, not to be removed by the most determined spirit. The thoughtfulness of genuine courage was at work. At 2 o'clock she took a good basin of beef-tea. At 3, a copious enema of

warm water ensured the clearance of the bowels. Drs. Blundell and Henry Davies, Messrs. Vincent, Beale, Burrows, Camplin, Hitchman, and Law, having assembled, and all necessary preparations being complete, at about a quarter before five o'clock Miss K. seated herself firmly at the end of a couch. It was observed immediately, though silently, by those who had witnessed them, that the abdominal tumefaction much exceeded that which existed in either case of my former operations. The pillows and bandage being adjusted as on those occasions, Mr. Beale took his post on the right, Mr. Law on the left of the patient: the former to manage the integuments, the latter the tumor. I sat obliquely facing the end of the couch, on her right.

Having no purpose of deviating in this case from my former plan of operating, though under no pledge to its invariable adoption, I proceeded to make the preliminary or exploratory small opening of an inch and a half in the linea alba, and below the umbilicus. Meeting with no unusual circumstance, unless the jet of a small artery be thought such, it was soon completed, and the abdominal cavity entered. The state of the cyst, as far the finger can ascertain it, was made out. A momentary pause was asked by my patient to draw breath. The wish was opportune, as the granting it gave time for the bleeding artery to contract. Having mentally measured, by the bulge of the abdominal skin caused by the tumor, of what size the incision need be, I now divided the integuments from above downwards in the median line of the abdomen, slightly deviating to the left at the umbilicus, and having reached the preliminary section at its upper end, I then prolonged their division downwards from its lower end to the requisite extent. Of the nineteen inches and a fraction, the distance from the point of the ensiform cartilage to the pubes, fourteen were occupied by this extended incision. When completed, I promptly took my curved probe-pointed bistoury, and by the guidance of two fingers of my left hand, divided the peritonæum from within to a like extent. An enormous cyst gradually advanced through the wound. Mr. Beale carefully and effectually covered the viscera by closing the integuments behind it. Mr. Law

sustained the weighty mass of disease. The broad uterine ligament of the left side constituted its pedicle, through which, under the protection of my own fingers, I thrust, from behind it, a needle armed with strong silk twist. The two halves of the pedicle were separately and tightly tied, and then it was divided between the ligatures and the tumor; the latter, weighing 28 lbs. being immediately removed without impediment from adhesion. No bleeding followed the division of the pedicle, which I tied with great force, having complete confidence in the strength of my ligatures, and believing that the period of their dislodgment depends much on the degree of constriction given to the substance of the pedicle in tying them. Having carefully but gently removed the blood collected at the lower part of the abdomen, and near the edges of the wound which had alone furnished it, I applied thirteen interrupted sutures; placed long pads of lint on each side, but a little away from the line of the wound, and over these applied strips of plaister, extending from one side of the body to the other, securing the whole by the bandage. Dr. Blundell had previously examined the other ovary, and found it healthy. Nothing could exceed the firmness of my patient's resolution. She had uttered no exclamation. Being now, however, somewhat faintish, she sipped a little brandy and water. After being placed in bed, slight vomiting occurred, and a very little brandy by itself was taken. An anodyne of gr. $\frac{1}{2}$ Morph. Acetat. in \mathfrak{z} ss. Mist. Campl. was given at about six o'clock, to be repeated in half an hour. I left her after the first had been taken with a pulse of 88.

10 P.M. — Had not slept; retched at 9, and brought up a little of the secretion of the stomach, slightly tinged with bile; complained of tightness at the lower part of the abdomen, as if the bandage were too tight, which I found was not so, nor was the plaister. Felt some tenderness on both sides of, and quite across, the lower part of the abdomen, but chiefly of the left side; and had pain in the back, and down the limb of that side. Urine drawn off, \mathfrak{z} ix.; pulse 105 to 108; no shivering nor chilliness: skin rather hot, but moist; temperature of the room, 72° F. Tongue clean; no headache, nor con-

fusion of mind; no bleeding from the wound; has drunk nothing but her medicine, and is not thirsty.

R. Ext. Hyoseyam. gr. v.; Morphiae Acetat. gr. ss. M. ft. pil. statim. sumend. A pint of water may be taken in the night, a little at a time.

13th, 8 A.M.—The vomiting recurred at 11 last night, and again twice between 5 and 6 o'clock this morning. Between 12 and 1 o'clock she fell asleep, and slept two hours, after which she dozed frequently. Urine was twice passed spontaneously, together to the amount of \bar{v} .; I drew off \bar{x} j. Though feeling better than she did last night, she says that her head aches a little, chiefly over the eyes, with a sense of "tired heaviness," but has no pain at the back of the head. Pulse 110, and rather full at the commencement of my visit, 102 at its conclusion; both carefully noted. Skin moist all night, but hot. Has taken nothing, not even the water, except one sip with the pill, and yet is not thirsty. Countenance animated, and with the colour of healthy warmth. Breathes freely without its hurting her. The sense of tightness at the lower part of the abdomen is less; but she feels it now all over, and she is sensitive over the cartilages of the ribs on the right side, but does not feel "the cut" much. Her back aches from the shoulder-bones all down the sides and legs, more particularly the left. Mind clear; no chills; no flatus; tongue a little furred at the back, and less moist than natural. Advised to take the water.

1 to 2 P.M.—Has slept nearly ever since my former visit, and the vomiting has not recurred. Urine drawn off, \bar{x} iv. I had cautioned her against any effort to pass it, lest the wound should be disturbed. Skin warm, and freely perspiring; tongue whitish; headache less, and feels better; pulse 98, full and soft. Temperature of the room 74° .

10 P.M.—Had dozed occasionally, and once slept an hour since my last visit. Pulse 112; tongue clean and moist. So little thirst that she has taken only about a pint of water since the operation, now 31 hours. Urine has been passed in considerable quantity; \bar{x} ij. only drawn off; natural in colour and other characters. A little flatus has been passed. Headache slight, but subsiding; mind clear; skin warm and moist. No shivering, nor

chilliness, nor sickness; and the vomiting has not recurred since 6 in the morning. Complains of some pain "in the lower part of the stomach (meaning, of course, abdomen), in the left hip, and back, and right ankle." Breathes freely, without fear of creating uneasiness. Felt as if she could eat some beef, when the nurse was taking her dinner.

Rep. Pil. ex Hyosc. Ext. et Morph. Acet.

14th, 8 A.M.—Has had an excellent night, with several hours of sound sleep, having been quite easy during the rest of the time. "At this moment I am free from pain altogether," is her answer to my inquiry how she feels. No vomiting, nor sickness, nor headache, nor confusion of mind, nor shivering, nor chilliness. No hiccup nor cough since the operation. Skin warm, and has perspired freely all night. Rather more thirst, but has taken only three quarters of a pint of water, and seems to wish for nothing in preference to drink. I inquired particularly on this point, as it was suggested to me that some fancy respecting water being likely to cause her complaint to reappear was existing in her mind; and I felt that to take rather more of it would cool and refresh her under the present slightly feverish state of her system. She has since assured me that she had no such idea, but really did not want more than she took. Tongue clean, except a little brownish tinge at the back, a common effect of opiates. Limbs and all other parts of the body now easy, "except just the bottom of the stomach since the use of the instrument" (the catheter), and of the limbs when moved. Urine passed and collected, \bar{x} ij.; withdrawn \bar{x} ij. only; but, as she drinks so little, and perspires so much, this is not surprising; it is higher coloured, in part, no doubt, from the same causes. Pulse 116, soft, temperature 74° —to be lowered gradually to 72° , and then to 70° .

I adjusted the dressings a little, but did not examine the wound. I ascertained, however, by very gentle examination, that the abdomen was quite free from general tenderness, as it was from distension, or even fulness in any degree.

Half-past 1 P.M.—Much as in the morning. Pulse a little quicker; but my friend Mr. Law having visited her

with me, and the patient being much pleased at seeing him, perhaps accounts for it. Has taken soda water occasionally, not quite in full action, and in very small quantities—a wine-glassful at a time. It refreshes her very pleasantly. Up to this time nothing but this and plain water have been taken.

To have a little arrow-root made with milk.

10 P.M.—Took her arrow-root, a tea-cupful, but not till 48 hours, at least, after the operation: enjoyed it. Is cheerful in countenance and manner. Has been a little uneasy with flatus, but is less so now, and thinks the soda water may have been the cause. Has dozed. Pulse 115, soft; tongue clean and moist; skin warm and perspiring; zvj . urine passed; ziss . only drawn off, to assume myself that it was duly voided. The power of discharging it is now complete, and the slight effort required is attended by no inconvenience. I had, however, discouraged the act to this time. No sickness, vomiting, nor hiccup; no shivering nor chilliness; no pain except a little “at the bottom of the stomach,” and some uneasiness in the legs, resembling rheumatism, she thinks, but very trifling. Slight headache, but no confusion of mind. No sense of inclination to relieve the bowels has occurred, nor flatus passed. Has no wish for more arrow-root, or any thing else. Dislikes pills, and would prefer a draught. Temperature 73. Pulse 111 at the conclusion of my visit.

R Tr. Hyoseyam. zss .; Morph. Acetat. gr. ss .; Acet. dist. gutt. v.; Aq. Menth. Pip. ssj . M. ft. Haust. h. s. s.

15th, 9 A.M.—Passed a quiet night, being quite easy, but slept little till between 7 and 8 this morning. Skin warm and perspiring; pulse 114; tongue moist, and very little furred at the back part. Flatus troubled her at one time, but does so no longer; some was got rid of. A sense of itching of the skin also teased her, but that has ceased. No sickness, hiccup, nor cough. Urine passed zvj . of higher colour. No distension of the abdomen; bears moderate pressure, even in the left iliac region. Limbs easier; back only feeling sore at its lowest part from lying constantly on it. More thirsty, and has taken a pint of water in the night; had previously not taken more than

three pints of liquid altogether since the operation. To have arrow-root. Temperature 72. Moistened the lint which adhered to the neighbourhood of the wound preparatory to dressing it at

2 P.M.—When I did so, and took out all the stitches. Adhesion throughout, even to the very spot where the ligatures lie, and only barely leaving open the space they occupy. No pus anywhere. I laid a narrow strip of lint with spermaceti salve along the line of wound; then placed a long pad of lint on each side, over which strips of mild adhesive plaster across the abdomen, and the renewed bandage gave the requisite support to the abdomen. Urine passed zvj .

To have a glass of calf's-foot jelly.

10 P.M.—Pulse 110, soft. Has had her linen and position changed, and is comfortable. She felt rather feverish from 5 to about 8 o'clock; but is not so now. The legs are uneasy, but for which she would, she thinks, get sleep. Urine passed zviii .; tongue clean and moist. Enjoyed the jelly, and would like another. To have it.

Repr. Haust. anod.

16th, 8 A.M.—Passed an excellent night, and is free from all uneasiness, that of the limbs having gone off soon after my visit last night, and before the anodyne had been taken. As it was too late to procure a jelly, took arrow-root with milk instead, and relished it. Was hungry in the night, and wishes for an egg and coffee for breakfast. To have them, with a little dry toast.

Urine passed zviii . rather high coloured; a little flatus. Pulse 104; tongue moist, and but little furred at the back; and this state is limited to the morning. Temperature 70, to be reduced to 68.

2 P.M.—The catamenia appeared this morning. Has been taken out of bed, and lies comfortably on a couch. Had a jelly since her breakfast, and no ill effect has arisen from either. Perspires gently; weather remarkably hot.

10 P.M.—Has had tea and a little toast. Skin rather drier. Has felt hot. Pulse 100, soft and full. It has always had the character of fulness, though this was not noted, as the degree of it was not so marked as it now is. Complains of nothing. Slept little in the day, but had a short refreshing sleep in the evening. Tempe-

perature 72, and it seems difficult to get it lower, though the aspect of the house is north, and there has been no fire all day. Tongue clean and moist. No motion yet, nor any inconvenience in consequence. It may be prudent to procure one in the morning.

R Extr. Colocynth. c. Extr. Hyoscyam.
aa. gr. vj. M. et div in pil. ij. h. s. s.

17th, 10 A.M.—Had an indifferent night, being twice affected with nightmare. Took some jelly, and this morning wished for the same breakfast as yesterday: pulse reported 95 before, about 100 after taking it. In all respects going on well.

2 P.M.—Wound dressed again. It is only a superficial line. In depth it is perfectly united, and the peritoneum has been shut from the first moment the wound was closed. No pus at any part of it, not even by the ligatures. Pulse 100. Has just taken some mutton broth with a little toast. Skin warm and perspiring. Temperature 72, and it was nearly or quite that in the shade out of doors this morning, where it is now hotter than in the house.

10 P.M.—Pulse 96, soft. Continues to menstruate, and has had a little bleeding at the nose, some few drops. Tongue clean and moist; and she perspires freely, rather too much so, particularly after sleep. Has slept on her "ligature side" for half an hour. Bowels not moved, nor has any thing passed from them since the operation, now full five days; nor have I seen any absolute occasion hitherto to disturb them, as there has been no abdominal distension or discomfort. Feels languid. As the pills seemed inactive, a copious enema of warm water was employed, and produced two abundant motions. A cup of sago with a glass of port wine was taken for supper.

18th, 8 A.M.—Her night was quiet, but she did not sleep much. The anodyne, ordered conditionally, and with a wish expressed on my part to discontinue its use if not really necessary, was not taken. Has made a good breakfast of egg, toast, and coffee, and felt to want it early. Pulse 92 full and firmer. Last night it was a little feeble. No return of epistaxis, but coughed once or twice slightly in the morning. Continues to menstruate, but very little. In other respects much as before.

2 P.M.—Pulse 88, after a dinner of ground rice pudding.

10 P.M.—In the course of the afternoon experienced a slight attack of gravel; and several little rough roundish concretions, consisting apparently of uric acid, were passed. She had taken soda water occasionally, in small quantities, during the last three days; and the alarm which this attack caused her being removed, she was directed to take it more freely. The urine had been rather high-coloured, and not very abundant; I have not noted the quantity. Pulse 83, soft and full. No motion. Sago and half a glass of wine for supper.

R Fel. Bov. inspiss. gr. x. h. s. s.

19th.—Passed a good night. In all respects comfortable. No more gravel has been voided. Wound dressed; a little thick healthy pus where the edges did not lie quite evenly together, also by the side of the ligatures, but in very small quantity. No tenderness at any part of the abdomen, not even in the left iliac region. In short, she is like a person quite well, one week from the operation.

10 P.M.—Pulse 80. More gravel was passed. No motion.

Enema aquæ tpid. To take the soda water freely.

20th.—A good night. Pulse 75. Bowels copiously moved; appetite good; urine plentiful, and much paler.

10 P.M.—Has had a comfortable day altogether, and slept in the evening. As she now eats rather heartily, it is desirable to keep the bowels free.

R Fel. Bov. inspiss. gr. x.; Aloes Barbado.
gr. j.; Pulv. Cinnam. c. gr. iv. M. et
div. in pil. ij. h. s. s.

21st, 1 P.M.—A good night, and feels quite well. Pulse 80. One copious pultaceous motion. In excellent spirits, and can hardly be restrained from singing. Can lie on either side, and in any position, with perfect ease. Wound dressed. Chicken and bread-sauce for dinner.

Rept. Pil. ij. h. s.

22d, 23d, and 24th.—Proceeding well. Wound dressed daily. It is a mere line; and the upper part of it, down to the umbilicus, chiefly healed.

Tr. Catechu applied.

25th.—Seems to have taken cold from a sudden and extreme change of weather. Pulse 90; and slightly feverish feelings.

R Extr. Colocynth. c. gr. v.; Hyoscyam.
gr. ij. M. et pil. ij. h. s. s.

Next day she was better; and at night, the pills, which had operated mildly, were repeated. She also abstained from meat. A fire in the room, and a bottle of hot water to her feet, had been useful.

On the 27th was again quite comfortable, with a pulse at 80. The wound, though for the most part healed, required the partial application of nitras argent., as some redundant granulations had sprung up, and one side of the skin was a little too high, and very sensitive, principally just below the umbilicus. The application produced an excellent effect in a few hours, particularly in reducing the sensitiveness, which was the chief cause of restraint upon her movements.

29th.—Walked across the room, leaning on the nurse's arm, and next day did so several times without support. From this time she has become more and more active and independent of assistance, getting out and into bed, and sitting up great part of the day. Remarkably little discharge has proceeded from the ligatures, and they have been left to themselves very much, except being carefully guarded from accident. She usually takes an aperient pill at night, but not always. It would be useless to carry the report further; and it may perhaps seem to some readers that the details are given more fully than necessary. To the really practical inquirer, I trust, they will not prove wearisome; as they are designed to assist in illustrating a subject with which very few are at all acquainted by actual observation. Having, however, with this view prolonged the narrative so much, it is not my present design to occupy the readers of the MEDICAL GAZETTE with many remarks.

The tumor itself requires but little description. A single principal cyst; a moderate portion of solid matter in a highly vascular condition; the fallopian tube stretching away to its fimbriated end, at a distance of some fifteen inches from the division of the pedicle; and the subjoined dimensions, are all the particulars that need be noted:—When lying, its circumference measured horizontally 3 ft. 8½ inches; vertically lengthwise 3 ft. 2 inches; and vertically across 2 ft. 10½ inches. It weighed 28 lbs. imperial weight.

Of the three cases of ovarian opera-

tion, which I have now placed before the profession, this one is perhaps the most interesting. It plainly demonstrates that, under proper precautions, the youthfulness of the patient need not deter the surgeon from attempting her cure; whilst the value of the relief afforded by the operation at such a period of life can hardly be over-estimated, when we consider the distressing annoyances to which the malady subjects a young unmarried woman in any station of life, more particularly one holding the position occupied by my patient.

Her recovery was in all respects more rapidly completed than that of either of my former patients.

With regard to the propriety of performing a formidable operation like this for such a disease, it may be briefly remarked that no means on which any reliance can be placed, except an operation, are, as far as I can learn, known to the most experienced *practical* physicians of the present day, any more than to those of past ages: none, at least, which unequivocally cure or mitigate the disease when arrived at such a stage as to require an operation. A mistaken idea prevails in some minds that the disease does not tend to shorten life, as well as to destroy its comfort. I shall hereafter shew that this opinion is totally at variance with facts. Like many other erroneous opinions, it is repeated on authority by men whose position might easily enable them to ascertain that it is devoid of truth. Compilers are apt to follow such men. How should they do otherwise? They themselves, with few exceptions, are little engaged in the observation of disease, and cannot be expected to form opinions, except upon the report of others. The rising generation of practitioners derive their instructions principally from men of these two classes, who thus propagate error from age to age, mixed up, indeed, with so much useful information as gives additional influence to the mischief.

Equally faulty in fact and in tendency is the suggestion that the operation itself is necessarily one of easy performance, requiring little anatomical knowledge, or skilful surgical adroitness. It may, indeed, be truly said of *any* operation, that the amount of mere anatomical knowledge required for the mechanical part of the surgeon's act is

not greater than a diligent student might acquire in a few months; and certainly not more truly of this operation, in which the separation of adhesions to the abdominal parietes and to the viscera themselves may be necessary: but it is the possession of correct physiological, pathological, and therapeutical knowledge that enables a practitioner to cope with the real difficulties of operative surgery, those which endanger his patient's life, or after-health and comfort. If to perform an operation so rapidly as to excite the astonishment of a large class of staring students, and for the sake of this worthless display to cause the greater mutilation of the patient, as in amputations, in order to avoid its consequences; if to disregard the preparation of the patient, so that dangerous symptoms must almost inevitably ensue; or so to mismanage the after-treatment that the patient's life is lost, when he might be otherwise cured; if to undertake without hesitation the performance of an important and hazardous operation in ignorance of those precautions which other men have shewn to be both necessary and effectual for the patient's preservation; if, in short, the dexterity of the mere anatomist be thus mistaken for perfection in the art of surgery; then, indeed, is it high time that such erroneous notions should be corrected, and that the profession should see the advantage of a different combination of qualifications for its *useful* exercise.

That the removal of dropsical ovaria by the large abdominal incision will become a legitimate operation in the hands of qualified surgeons, there can, I think, remain but little doubt on the minds of practical men who have looked into the subject; I know that many such already consider the operation as established by the cases of Dr. Clay and myself. My own experience confirms me in my opinion of its humanity, usefulness, and practicability, when properly conducted in well-selected cases; and that, so conducted, it will be the means of averting much suffering, and saving many valuable lives, I entertain not the slightest doubt. As a comparative novelty, however, it has to contend with unjust prejudice on the one hand; with ignorant rashness on the other. The former will gradually give way to conviction, or be reduced to silence; but

the latter, in its reckless eagerness for distinction, may do much mischief by its unjustifiable proceedings, and so bring into undeserved obloquy what will otherwise be deemed a valuable improvement in surgery.

Guilford Street, Russell Square,
London, Oct. 3, 1843.

SULPHATE OF POTASS.

To the Editor of the Medical Gazette.

SIR,

IN an article entitled "Two late Coroners' Inquests," inserted in the last number of the *MEDICAL GAZETTE*, Oct. 6th, you have remarked, that "should it turn out that death was occasioned by sulphate of potass (as you are inclined to think it was), this will be the first case on record of poisoning by that neutral salt." Agreeing with you as to the cause of death, for the reasons to be adduced presently, I beg at the same time to refer you to several recorded cases wherein this remedy has occasioned symptoms of poisoning, and in some death. Moreover, whilst at Auxerre, Yonne, in 1839, it was stated to me by a *confrère*, one of the professors at the College, that the abuse of this salt, with a view to produce abortion, was notorious to the midwives of that department of France. At that time I conceived it to be so harmless a salt, as its name *sal polychrest* would lead us to infer, that I deemed it prudent to tolerate such a popular idea, rather than question its accuracy by the expression of a contrary opinion. Subsequently, however, the poisonous properties of this salt, when administered under certain conditions, were confirmed in my own mind by a case reported by M. Chevallier, one of the talented *collaborateurs* of the *Journal Médicale*, in the June number, 1842, of that work.

M. C. states, that the death of Madame B., in October 1841, was occasioned by this salt. This lady had been recently confined, and her medical attendant had directed 40 grammes, = 1 oz. 12 grs. T., of sulphate of potass, to be administered in six doses of 100 grains each. Death ensued in less than two hours after the remedy had been administered. Analysis of the contents of the stomach removed any

suspicion as to the purity of the salt, and left no reason to doubt but that death had been caused by the salt alone.

CASE II.—Mrs. H., a nurse, administered pursuant to the instructions of the medical attendant, 8 grammes, = 2 drachms, of sulphate of potass. The dose was sufficient to cause such symptoms as led the practitioner to imagine that the patient had taken poison.

CASE III.—In the *Dict. Univers. de Matière Médicale*, p. 485, MM. Merat and Delens state:—We were witnesses, in 1821, that 30 grammes, = $7\frac{1}{2}$ drachms, of sulphate of potass, taken by mistake for Seidlitz (Seignetto?) salt, caused a kind of poisoning (burning sensation, pains in the epigastric region, vomiting, &c. &c.)

CASE IV.—M. J. G. Greisel relates, in the *Univ. Acad. Nat. Cur.*, Dec. 1, 1672, p. 77, that the action of 2 grammes, = 30 grains, of this salt, caused excessive purging, ending in death, to a patient suffering from fever; but M. G. observes, that it is owing more to the inopportune employment of this salt, than to its excessive activity, that such grave accidents result from its use.

CASE V.—M. Gardien has remarked, in the *Dict. des Sciences Médicales*, vol. vii. p. 165, that very small doses of this salt irritate the stomach and bowels of delicate women.

CASE VI.—M. Sobaux cites four cases by which he seeks to demonstrate that this salt is very apt to prove injurious, giving rise to serious accidents. Lastly, I may state, as coming under my own observation, symptoms resembling those occasioned by corrosive poisons supervened where a dose of four drachms of this salt had been administered to the wife of a friend immediately after her confinement. The facts mentioned at the commencement of this communication, when suggested as an explanation to the medical attendant, only drew forth an incredulous shrug.

Perhaps, if you think this letter worthy of insertion, some practitioners, regarding the authorities quoted as entitled to consideration, may take an opportunity of furnishing, through the medium of your pages, the result of their experience. A farther benefit may, indeed, arise from it, that those who are only protected by the *diploma* of the Pharmaceutical Society may ob-

serve caution in recommending what are termed harmless medicines; for by the authors most frequently consulted by counter-practitioners, the dose of sulphate of potass is stated to be from ten grains to four drachms; and, indeed, Dr. Christison observes, this medicine is termed a mild cathartic and convenient laxative, undeserving of the neglect into which it has fallen.

I am, sir,

Your obedient servant,

G. M. MOWBRAY.

ON VIVISECTION.

By ROBERT HULL, M.D.

(For the London Medical Gazette.)

“WEINHOLD took away the brain and spinal marrow of a cat, and filled the skull and vertebral canal with an amalgam. Life appeared to be restored, the animal lifted its head, opened its eyes, and, with fixed stare, endeavoured to walk; and, when it dropped, tried to raise itself. It continued in this state twenty minutes.”

This diabolical business was meant to illustrate the “power of galvanism.” I wish the law of those dominions could serve the operator in a similar manner. The Lex Talionis approves itself to our native sense of justice. What evidence is now wanted of the power of galvanism?

In this country Martin's Act might be brought to bear on similar diablerie. Such executioners are beyond the reasoning appeal; their feelings are unnatural. They endure no pangs in their processes of torture; they chuckle under the excitement. They cannot understand that unworldly philosopher, Sir Charles Bell, who wrote to his brother, “I cannot proceed without experiments, which are so unpleasant that I defer them. I cannot convince myself that I am authorised in nature, or in religion, to do these cruelties.”

“He was not of the Frenchified butcherly school of anatomical experimenters. We think Orfila boasts of having sacrificed the lives of *ten thousand animals* in his researches into poisons.” Thus speaketh the Quarterly Review. I would exhort the govern-

ment of that land in which is performed such coward cruelty—*Hanc tollite ex civitate, iudices, hanc pati nolite diutius in hac republica versari: quæ non modo id habet in se mali, quod tot animalia atrocissimè sustulit, verum etiam hominibus lenissimis ademit misericordiam consuetudine incommodorum.*

This Christian philosopher might have interpreted liberally the Pagan sentiment—*Incidere vivorum corpora et crudele et supervacuum est.*

Parents will do well to preserve their children from the butcherly schools, lest their ingenuous hearts be hardened *consuetudine incommodorum.* For the transit from less to greater horrors is easy. He who is callous to the supplicant moans of an unprotected, impotent quadruped, will soon be deaf to the shrieks of a man. He is not far from the diabolism of Messrs. Herophilus and Erasistratus, qui nocentes homines à regibus et carcere acceptos, vivos inciderint, considerarintque etiam, spiritû remanente, ea quæ natura ante clausisset.

Mr. Macilwain, a surgeon of literary and operative fame, has been long impressed with the inutility of vivisection, its inconclusiveness, its immorality. This is just what the medical world should learn; he has stated it in his philosophical work on "Medicine and Surgery." I hope his *proofs* will be published.

The nauseating experiments on unprotected animals, made to elucidate the sounds of the heart, bear little, if any, proportion to their vaunted utility. I believe *none.* I am unwilling to allude to the performances of Dr. Hope, simply because he is dead; but I declare that I cannot reconcile the barbarism of his numerous vivisections with the superiority claimed for his religious character. This appears to be so dear to a certain section of professors that I know his biography is purchased and distributed to men of "doubtful views." But he is thus peculiarly brought—works, memoir, all—before the public tribunal; and I have a right to pronounce my humble sentiments. See the exclusiveness claimed for his piety by theologous Almack's. "He felt Dr. Burder especially endeared, as the *only one* of his professional brethren from whom he could ask advice founded on religious principles." Is this, or is it not, a calumny?

Very many members of the medical profession, and they practising and accessible in the metropolis, deserve in every sense of the terms to be considered as good and exemplary christians. They may not belong to a pharisaical clique; nor cant the shibboleth of a miserable party; but, with a dignified, unobtrusive, *quiet* piety, they are passing through this probationary state, doing their duty to man, giving his glory to God.

————— σπάνις
τῶν ἀγαθῶν —————

may be true enough comparatively; but they are not yet reduced to "one."

To me it is surprising that persons who set themselves up as moral censors should contemplate with complacency the sufferings of innocent animals. Before me lies an essay, written against all stimulant drink, by one Ralph Barnes Grindrod, who quotes without any reprobation alcoholic experiments on animals, in comparison with which drunkenness is a virtue. Worthless, puerile, murdering manipulations, performed on God's creatures, quite as meritorious as Messieurs Rayer, Majendie, Sigelas, Grindrod, or the whole sect of water-drinking fanatics put together.

"Thou shalt not do evil, that good may come?" As a believer in Christianity, I hold that this proposition extends to helpless animals. I firmly believe that it excludes vivisection from the pale of morality. I boldly declare that nothing can justify vivisection. It is a damnable process! and I close my ears to the heartless sophists, who twaddle in its defence. Great philosophers, undoubtedly, have tormented their fellow-animals; and prodigious discoveries have been trumpeted as the result; but I believe that no discovery, worthy the name, has been logically due to this diablerie. Read Harvey, De Sanguinis circulo; and say, if the anatomy, the physiology, the symptoms, did not make out, by his own showing, the circulation of the blood; all his vivisection being as superfluous as it was infernal.

All subsequent butcheries, for chirurgic or physiologous ends—from experiments for aneurism and inflammation, down to those on the excitatory system—I believe to be supererogatory, and as puerile as savage.

To these remarks I am animated by a simple sense of duty and humanity ; and so imperative do I feel the impulse, that, if I held my peace, I should deserve the caustic objugation of Andromache :—

μισήφρονον μὲν οὐκετ' ἂν φίλοι μύσος
ἐν τοῖς δὲ πολλοῖς καὶ σὺ τόνδ' ἀγῶνι
φόνον.

Norwich, Oct. 2, 1843.

CASE OF CANCRUM ORIS.

By ROBERT DUNN, Esq.

(For the London Medical Gazette.)

S. RIDLEY, aged 2½ years, was brought to my house, by her mother, on Saturday, Sept. 16. The child had an expression of heaviness about the eyes ; the skin was hot, and the pulse quick ; the mucous membrane of the mouth was in an unhealthy state, and the gums were spongy ; there were blotches upon the body, resembling the pustular form of scabies ; the child was of a cachectic habit, arising from the combined influence of an *unhealthy locality* (Windsor Court, in the Strand), and *defective nutrition*. It was scarcely possible, indeed, for it to be otherwise, from the terms upon which the parent of the child lived. I have often pitied the poor children. Within the last few months, the mother nearly lost her life from *flooding*, in consequence of a *miscarriage*, occasioned, as she stated to me, “by the kicks and blows, and brutal treatment, of her husband,” and the external marks upon her body gave awful proof of acts of violence. I have been called upon to furnish a certificate of her inability to appear at Bow Street Police Office, on account of *family differences*. I think it necessary to state these facts. They are important in a medico-legal point of view for forming a just opinion on the conflicting testimony in the evidence of the case, but still more in reference to the effects of *defective nutrition* and the formation of the cachectic habit. How children, living in such a vitiated atmosphere, and neglected as I have seen them, could escape constitutional deterioration, it is difficult to conceive. I prescribed for the child a mixture of carbonate of magnesia and soda ; three alterative powders, each containing P. Rhei, gr. iv. ; Sodæ exsic. et Hyd. c.

Cretâ, aa. grs. ij. alternus noctibus sumendus ; and some camphorated sulphur ointment to be applied to the blotches. One only of the powders was given. On the Monday morning I was asked to visit the child in Windsor Court. I found the eruption of measles was coming out, but not freely ; the child was in a low, drowsy state ; pulse quick, but weak ; skin hot and dry ; bowels much relaxed, with pneumonic indications. The feet were put into hot water with mustard ; cataplasms of linseed meal were applied to the chest and between the shoulders, and cretaceous medicine with ammonia administered. There was great prostration of the vital powers, and so much stupor, that strong mustard poultices did not arouse the child, nor elicit any expression of pain or uneasiness. The eruption was not properly developed, and on Wednesday the measles disappeared, leaving her in a very low and depressed condition. My attention was now directed to the state of the mouth and gums, and about which I questioned the mother. Previously to the child's illness the gums had bled frequently, and the mother feared this might arise from using a small brass ring, with which she played at school ; the texture of the gums was now of a livid hue, and spongy. I observed at the junction of the gums with the lining membrane of the lower lip, in front of the mouth, a number of small yellow spots, resembling aphthæ, and giving vent to a whitish exudation ; the intervening mucous membrane was tumefied and red. I ordered some borate of soda with honey to be applied frequently, with a camel's hair pencil ; ten grains of the compound jalap powder to be given, and a saline mixture, with ammonia. Next morning, in cleaning the aphthous spots with the brush, I perceived irregular ulcerations with ragged edges. These ulcerations, for the next three or four days, slowly but gradually extended, assuming a dirty grey appearance, and were covered with a tenacious purulent exudation. The breath, which was fetid from the first appearance of the ulcers, now became almost intolerable. The same kind of aphthous points appeared, two or three days subsequent to the first, on the upper lip, right cheek, and gums, and quickly passed into the same state of ragged ulcerations. A lotion of

chloride of soda was kept almost constantly applied, and every means to support the child had recourse to; ammonia, quinine, beef-tea, and port-wine, &c. but without effect. The disease gradually progressed in the *dry form*, the *forme charbonneuse* of M. Taupin; the gums of the lower jaw were reduced to a black fetid pulp; the child herself removed the whole of the teeth from it, with her fingers, one by one; the lower lip and chin became swollen, soon passing from a reddish hue to a dingy yellow colour, having the cellular substance extensively infiltrated with yellow serum. The first external eschar appeared upon the chin, about a week after the appearance of the measles, and rapidly increased in size, changing from a dirty yellow to a black colour; the cheek and gums, and upper lip on the right side of the face, as well as the lower lip and chin, were connated, before the poor child died, into a black, soft, and homogeneous mass, and giving out a most intolerably strong gangrenous fætor. The child died on the 1st of October, fifteen days from the time I had first seen her. My friend Dr. Todd, of King's College, kindly saw the case twice with me during the progress of the disease. A coroner's inquest was held upon the body, under the suspicion that the child had died from the effects of mercury. It was alleged that instead of the 10 grains of compound jalap powder, which I had prescribed 12 days before her death, a slate-coloured powder, 10 grains of the Hydr. c. Creta, had been sent, and was given. How far this allegation can be supported by any degree of probability, I must leave to be deduced from the history of the case, the character of the parents, and the fact that the gentleman who dispensed the medicine is now in his third year's attendance on the medical and surgical practice of King's College Hospital. The most correct report that I have seen of the coroner's inquest appeared in the *Morning Post*. Mr. B. Brooke, 27, Bedford Street, surgeon to the Strand Union, who made the post-mortem examination by order of the coroner, satisfied the jury that the child died a natural death, and offered it, as his opinion, that no medicine, not even mercury itself, could produce the disease.

Dr. Todd bore testimony to the spe-

cific character of the disease, and to the correctness of the treatment which had been pursued. Mr. Walker, surgeon, of Drury Lane, who had been surreptitiously called in by the mother, voluntarily came forward, and nobly bore the same testimony. Mr. Brookes gave the following brief account of the post-mortem appearances:—"The right side of the face, half of the nose, upper and lower lip, were perfectly black. Upon carefully examining the inside of the month, there was observed great ulceration of the gums. The alveolar processes were denuded, and the teeth gone. Half of the tongue was black, and the inside of the cheek and fauces gangrenous—the whole exhibiting the *true cancum oris*, or gangrene of the mouth. The stomach was perfectly healthy, and the small intestines diaphanous."

During the last week, indeed on the very day upon which the inquest was held, I was called in to another case of the *metastatic* variety of the cancerum oris, supervening upon measles also, in a boy four years old, in Castle Street, Leicester Square, and attended by Mr. Skegg, of St. Martin's Lane. Here the attack came on without any premonitory indications. A small tumor formed in the inner surface of the cheek; a gangrenous appearance supervened, and the breath became extremely fetid. Externally, the surface of the cheek became tumid, reddish, and shining. A lotion of chloride of soda was assiduously applied, and quinine and liquor sarsæ freely given. The slough separated: the opposite side became in the same way affected. The second slough has come away, and the child, under the quinine, sarsæ, and generous diet, is now gradually progressing to convalescence.

15, Norfolk Street, Oct. 10, 1843.

MEDICAL GAZETTE.

Friday, October 13, 1843.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

A FEW WORDS TO STUDENTS.

IN the hints which we ventured to address to pupils a twelvemonth ago,

we observed that the first error which they often commit, the error, namely, of living in lodgings, instead of forming an integral part of a family, is the parent of a hundred more. But the more we consider the subject, the less blame shall we attribute to the unfortunate student himself, and the greater to those who have indiscreetly left him a choice in a point where his age renders him incapable of judgment. The selection of a school, too, cannot with propriety be left to a youth of eighteen; who may be easily led astray by offers that would be heard with incredulity by his parents. Nay, even so poor a temptation as the addition of ten pounds to their pocket-money might seduce some to prefer brass to gold, and to put up with the manifold imperfections of schools which have nothing to recommend them but their cheapness. Uninfluenced by these paltry considerations, the parent to whom years have brought experience as well as grey hairs, will choose a school where the teachers are eminent for the sciences which they profess; and when circumstances admit, he will be influenced by the same principle in his selection of the house which is to be the asylum of his son in the metropolis.

For, it is thought, and with justice, that the proximity of high talent has somewhat vivifying, and that it is impossible to enjoy the social intercourse of a first-rate man, without being inflamed, occasionally at least, by the scintillations of his genius. When we read, for instance, as we still do from time to time, that a lately deceased practitioner was a pupil of John Hunter, we feel that we have lost one whose opportunities of professional improvement were boundless; who was taught, not only by direct instruction, but by casual hints; who was not only admitted to the feast of science, but might boast of his participation in

the crumbs which fell from the rich man's table. And if these grains from the golden stream—these precious fragments carelessly borne along by Pactolus—are received in a fit reservoir, the effect is noble indeed! *Quodcumque recipitur*, say the schoolmen, *recipitur ratione recipientis**. The ancient sage, when asked what men should learn when young, answered, that which will profit them when old; and we should advise the parent, when he selects a family for the abode of his son, to fix on one whose example he would wish him to follow in after-life.

Those students who are happily anchored within the safe roads of a Collegiate establishment, or the quiet haven of a private family, will hardly need our advice as to the best method of spending their time; those who are less fortunately situated will not be the worse for our counsel.

During the first winter session the pupil can hardly spend too much time in the study of anatomy. A lecture on anatomy, an anatomical demonstration, and his own dissections, will fill up great part of the day, and will leave him just time enough to attend lectures on chemistry and on *materia medica*. The latter may now be divided into two courses of fifty lectures each, one of which may be attended in the summer†.

* We may suppose Darwin to have been inspired by the society of Watt, when he exclaimed, in 1791—

"Soon shall thy arm, unconquered STEAM, afar
Drag the slow barge or drive the rapid car!"

Another time, at one of the meetings of the scientific club, to which they both belonged, Darwin said, "I have formed an idea of a duplex pen, a pen with two quills, by help of which one may write two copies of anything; which will thus, at a single operation, produce both the original and the transcript of a letter."

"I believe," replied Watt, "I can find a better way of solving the problem: I shall think over it to-night, and communicate my ideas to you to-morrow." By the morrow, the copying press was invented, which has been adopted, with some improvements, in half the counting-houses of England.—*Gentleman's Magazine*, Nov. 1841.

† Vide the new regulations of the Society of Apothecaries, in our number for the 22d ult.

If the study of anatomy is not deferred to the last moment, but is begun, as it ought to be, during the earlier part of the pupil's apprenticeship, it would be well to add comparative to human anatomy, and study the frame of animals as one great whole. But those who have trifled away whole years in pounding medicine, or in employments even less laudable, far from affording this luxury of science, will often have to endure that most painful of privations, a minimum of knowledge!

As for taking notes, it can scarcely be advisable to do so habitually in the anatomical theatre, except during the physiological part of the course; yet not only there, but in the dissecting room, points may sometimes occur, worthy of being inserted among the student's memoranda. On the subject of notes, Dr. Thomas Young expresses himself with his usual lucid good sense.

"The practice of taking notes from lectures is of clear and decided utility: and every student ought to make it a point to keep correct and complete notes of one course of lectures on each department of medical science. But it will seldom be advisable to take notes of a first course, where two or more are to be attended; in order that the mind may, in the first instance, be wholly devoted to following and comprehending the lecturer. The use of shorthand I consider as every way to be reprobated: it converts the writer into a mere machine: it employs him in copying words, instead of digesting and compressing thoughts; and unless he has two or three more hours to bestow on the same subject after the lecture, which very few lectures are worth, his manuscript remains in a form almost as inconvenient for reference as if it were written in an unknown language."*

When the student attends a hospital, we strongly urge him to take, and to keep, notes of the cases. When medical schools shall emerge from the embryo

state in which they now slumber, and shall be carried on with a zeal proportioned to their importance, the student will no longer be recommended, but commanded to take notes. If not his teachers, the state will interfere, and will not let loose those who have neglected the most obvious means of instruction, to practise upon their defencless fellow-creatures.

It is to be wished that case-books were published, printed under the sanction of some of our principal physicians and surgeons, as a guide to the student and the practitioner. At present, we blush to say, there are learners of the healing art who keep no note-books whatever of cases!

The student when he begins to attend cases for himself must put down a diagnosis in every instance, with the reasons which have led him to draw it. Erroneous diagnoses will lead in time to true ones; and we shall no longer be startled by such shirkings of the question "as disease of the chest" in the registers of mortality.

We gave the new regulations of the College of Surgeons in our number of the 1st ult., and those of the Society of Apothecaries on the 22d ult.

The Worshipful Society, after setting forth the course of study in all its details, observe that "the above course of study may be extended over a longer period than three winter and two summer sessions, provided the lectures and medical practice are attended in the prescribed order, and in the required sessions."

If we understand the programme aright, the only subjects which the pupil can push beyond the limits of the three winter and two summer sessions are, midwifery, with the diseases of women and children, and practical midwifery.

If we are not mistaken, these subjects, and these alone, may be delayed, and the five sessions be thus relieved

* Young's Med. Literature, 2d Edit. p. 13.

of part of their overplus. If we *are* mistaken, we should be glad to be told so, as the subject is of some importance.

In the previous set of regulations it was doubtful, as we pointed out on a former occasion*, whether the student was required to attend the medical practice of a hospital for eighteen months, or might attend a hospital for twelve, and a dispensary for six months. This doubt is now cleared up, and the choice just mentioned is left to the pupil. We cannot suppose that this has been done to spare the pupil's purse, as hospitals in general have accommodated themselves to the Society's regulations, and require no more for eighteen months' attendance than for twelve. Even where this has not been done, the difference is very trifling, and even less than the slender fee of a dispensary. We therefore suppose it may have been done to give the student the opportunity of seeing different styles of practice, and modifications of disease; and if dispensaries were somewhat better conducted, this would be a valuable result of the permission.

We need hardly hint to those who do not confine their medical studies within the narrow limits of legal obligation, that some diseases, as they have obtained special hospitals for their cure, so, likewise, they deserve a special study. Among these we may mention fever, syphilis, diseases of the eye, and insanity. The diseases of the mind, in particular, attract more and more of public as well as of professional attention; and those who are not too eager to begin the pursuit of their profession the very moment they have obtained their license or diploma, will do well to study the aberrations of human reason, and the modes of rectifying them†.

Before concluding, a word to the

hypochondriac student—to him who fears that the crowd of competitors must render his success impossible, and that his talents will be unrewarded, because unseen. Let him be assured that the public are as desirous to enjoy the services of men of talent, as these are to reap the reward of their merits. The attorney is as solicitous to procure an effective advocate, as the young barrister can be to catch the briefs which are flying around him. A nobleman, when ill, longs as earnestly for the aid of a skilful physician as any physician can desire practice among the nobility.

Hence, although knowledge cannot be brought to market with quite the same ease as material substances, it ultimately meets with eager purchasers; and talents, whether brilliant or solid, are nearly as certain of finding a market as diamonds or Portland stone.

Finally, let the student whose time is not limited make use of this splendid advantage; and let him of scantier means balance the unkindness of his fortune by the intensity of his diligence, so that his years of study may seem long, when we consider how much he has crowded into them:

*Quid numeras annos? vixi maturior annis;
Acta senem faciunt; hæc numeranda tibi!*

COMPLIMENT TO THE MEMORY OF SIR CHARLES BELL.

SIR ROBERT PEEL has addressed the following letter to Lady Bell:—

“Whitehall, Sept. 4.

“MADAM,—I have had great pleasure in recommending to Her Majesty, that in consideration of the high attainments of your lamented husband, and the services rendered by him to the cause of science, a pension of one hundred pounds per annum for your life, shall be granted to you, from that very limited fund which Parliament has placed at the disposal of the Crown for the reward and encouragement of scientific labours.

This pension, small in amount as it

* MEDICAL GAZETTE, Sept. 30th, 1842.

† We had the pleasure of informing our readers last year that St. Luke's had been opened to pupils; and it still remains so.

necessarily is, will perhaps be acceptable to you, as a public acknowledgment on the part of the Crown of the distinguished merit of Sir Charles Bell.

I have the honour to be, madam,
Your faithful and obedient servant,
ROBERT PELL."

VITAL STATISTICS OF SHEFFIELD.

To the Editor of the Medical Gazette.

SIR,

THE distressing account of the fork-grinders of Sheffield, and your benevolent appeal on their behalf, given in the *GAZETTE* for September the 8th, suggest the propriety of any one who has a hint to give on this vitally important subject to give it forthwith, in the hopes that it may arrest the attention of some one, or more, who may have the power to enforce, or rather to introduce, its adoption, if practicable and effective; or, by causing others to put "their brains in steep," elicit some more efficient protection against so dreadful a mortality as that among the fork-grinders.

You suggest "the substitution of *wet* for *dry* stones:" surely if this had been "practicable" it would never have been otherwise. Humanity forbids any other conclusion. May we not, then, fairly conclude that a plan, at once so simple and so obvious, cannot be adopted? Magnets have, I believe, been tried; such means would of course only retain the metallic particles, and even these perhaps but partially. Myself the subject of asthma, and liable, at one time, to a recurrence of this troublesome, though far from fatal disease, on inhaling any irritating gases, I remember to have descended, leisurely enough, a rather long flight of stairs, at the bottom of which was burning a great bundle of straw, that had been accidentally ignited. In the midst of this very suffocating smoke I respired, really quite freely, for, of course, some seconds; and this I did by applying a silk handkerchief, once or twice folded, closely over my nose and mouth. I have subsequently enabled asthmatic patients, by the same method, to work comfortably in the most dusty atmospheres, for hours at a time; for example, in turning over wheat, &c. in large granaries. Could no modification of a plan so simple and economical be adopted with the operatives in question? It really appears to me that two plies of silk, extending from the bridge of the nose downwards to below the chin, and laterally over each cheek, with perhaps an elastic pad—of horse-hair or the like, sewed up in silk—on each side of the nose, and an elastic band over the vertex, with another horizontally

over the occiput, to retain the whole in situ, would go far, if not entirely, to put a stop to so fearful an expenditure of human life. It is understood that the mortality among such of the stone-masons as labour at the finer kind of work in Scotland, where the stones are "dressed" *under cover*, more or less complete, is decidedly greater than it is among the same class of men in England, where such operations are carried on, more or less completely, *in the open air*; a statement which, if correct, is too important to be lost sight of in the present instance. Again, Dr. David Boswell Reid used fearlessly to experiment with the arseniuretted hydrogen, and other deadly agents, before his numerous class, over a powerful *descending current* of air, obtained by opening up a horizontal branch of a long chimney leading from a furnace.—Believe me, sir,

Yours very truly,
R. E.

October 7th, 1843.

EDINBURGH DEGREES.

To the Editor of the Medical Gazette.

SIR,

It is some time since I first addressed you on the subject of "Medical Officers under the Poor-Law, (vide p. 432). My communication elicited two replies—the first from "Edinburgo-Londinensis," who adduces *one* example of non-removal from office, certainly creditable to the honesty of the Poor-Law Commissioners, but nothing is brought forward by him to meet what is *implied* in the statement to which I alluded, namely, the qualification. The second letter, that from Mr. Wolseley, does give the information sought for, in the reply made by Mr. Chadwick "that medical practitioners possessing only a Scotch qualification are not legally eligible for the appointment of medical officers in England." Those elected will not be removed, but in future none unpossessed of both a London College of Surgeons' diploma, or the Apothecaries' Company's license, will, in future, be elected. The North of England Medical Association have, through its Council, pointed to this "unjust restriction," (vide p. 221) which, from your report of their meeting, I find affects not only the Scotch, but the Irish University and College of Surgeons. The Medical Association of the North of England, and all the medical associations of the kind, should unite in removing such an odious restriction on their brethren of the sister kingdoms. From whence have been, of late years, many valuable instructors derived by the schools and colleges of London? From Edinburgh. From whence much valuable,

much original information? From Dublin. Yet the students of these schools are, in after life, as practitioners in England, to be declared unqualified by the Poor-Law Commissioners; and the only mode of obtaining their licent is to pass an examination at the Royal College of Surgeons, London, and the Hall; or, in other words, to pay a limited sum of money as "a footing" in England.

One question in conclusion.

What is the legal value of a medical degree conferred by the Senatus Academicus of the University of Edinburgh?

If no one among your correspondents can reply to this, the Dean of Faculty at Edinburgh can, if he will, I presume.

I am, sir,

Your obedient servant,

E. M. R.

Sept. 28, 1843.

NITRATE OF SILVER IN OPHTHALMIA.

M. VELPEAU has endeavoured to distinguish the circumstances which should regulate the various modes of employing the nitrate of silver; but as they are all founded on anatomical differences, they seem to us of little use in practice. The employment of the nitrate of silver ought to be founded, not on differences of form, which are very difficult to ascertain, and which are often quite arbitrary, but on differences in the nature of the ophthalmia. There are many kinds of severe ophthalmia in which the nitrate of silver is very efficacious; among these is the purulent variety. In this kind of ophthalmia, which is often connected with some internal disorder, and which is frequently epidemic among children, M. Velpeau proposes to use from one to two parts of the nitrate of silver, dissolved in thirty parts of the vehicle. M. Baron, however, says that in the Foundling Hospital, where this form of ophthalmia is very common among newborn infants, a much stronger solution is found necessary; the proportions being from eight to sixteen parts of the nitrate of silver to thirty of water.—*Gazette Medicale*, Oct. 7, 1843.

REMEDY FOR HYDROPHOBIA.

By DR. ASMUS.

THE history of the remedy is as follows. The Thömer family at Stolp possessed the receipt as long as any could recollect, and distributed the medicine. Chemical examination did not succeed in discovering its composition. Often as it had been used, no case was known where hydrophobia had appeared after its employment, not even when

the first symptoms had indubitably begun to manifest themselves. The directions are, that the person bitten is to swallow three times as much of the powder as can be taken up with the point of a knife, for three days running, in the morning. It is to be taken fasting and in warm beer, and the patient is to wait till perspiration comes on. No particular diet is required, nor scarifying or cauterizing of the wound. Many respectable persons pledge themselves to the unusual efficacy of this remedy, which was communicated to Dr. Asmus by the last Thömer. Its composition is as follows:—

R. Lap. Canceror. ppt.; Pulv. rad. Gent. rubr. aa. ℥ij.; Bol. rubr. ℥j.; Gummi myrrhæ, ʒss. M. ft. pulv. subtilissimus.
—*Veterinarian, and Schmidt's Jahrbücher.*

FILARIE IN THE BLOOD OF A LIVING DOG.

MM. GRUBY and Delafond communicated to the Academy of Sciences the discovery of the entozoa circulating in the blood of a strong and healthy dog. Physiologists have for a long time been aware of the presence of certain entozoa in the blood of reptiles and fishes, but this is the first instance in which they have been detected in the blood of a living mammal. It is of high importance to physiology, pathology, and natural history, to show not only the existence of worms in the blood, but also their circulation in this fluid, in the animals which come near to man in the scale of organization. These entozoa have a diameter of 0.003 millimetre, and a length of 0.25 millimetre. These bodies are transparent and colourless. Anterior extremity is obtuse—posterior or caudal extremity is terminated by a very slender filament. At the anterior part may be observed a little round depression, 0.005 millimetre long, which may be considered as the buccal fissure. Their motions are very active. Their life has been prolonged ten days after the blood has been taken from the vessels, and exposed to a temperature of 15° centigrade, or 59° Fahrenheit. They swim among the globules of the blood with great vivacity, exercising an undulating movement. MM. Gruby and Delafond found them in the blood taken from the coccygeal arteries external jugular veins, capillaries of the conjunctive, mucous membrane, skin, muscles, and every where this liquid was found to contain them. The urine and other excremental matters did not contain them. The diameter of these entozoa being less than that of the blood corpuscles, enabled them to circulate through the capillary blood-vessels.—*Comptes Rendus*; and *Physiological Journal*.

EXTIRPATION OF THE SALIVARY GLANDS IN ANIMALS.

By M. BUDGE.

IN his researches on the saliva, M. Budge constantly found that fluid alkaline, before as well as after a repast. This alkine reaction was found to exist in animals even after a prolonged fast. To ascertain what effect the salivary glands had on the alkalinity of the buccal secretions, M. Budge extirpated the whole of the salivary glands of a dog, viz. the parotids, submaxillary, and sublingual glands of both sides. The dog survived the operation, but the buccal secretions were constantly found alkaline. When the dog was killed at the end of a month, the fluid of the stomach was found slightly acid. The same operation was repeated in a rabbit, and with the same success,—the buccal secretions remained alkaline. — *Medicinische Zeitung*, November 1842, and *Edin. Med. and Surg. Jour.* October 1, 1843.

SYDENHAM SOCIETY.

To the Editor of the Medical Gazette.

SIR,

WOULD you allow me, through your columns, to hint to the Council of the Sydenham Society, that medical biography would be a subject well worthy of their attention, for publication. A volume of Hunterian Orations, or selections from them, would be very acceptable to the members, and would be an excellent account of the life of John Hunter, and also of a great number of others whose lives are sketched in the different orations, and also would give the style of writing of the most eminent surgeons of late days.—Yours,

A MEMBER.

Sept. 1843.

GULSTONIAN LECTURES,

*Delivered at the College of Physicians,
February, 1843.*

By GEORGE BUDD, M.D. F.R.S.

Professor of Medicine in King's College, London.

LECTURE III.

IN my last lecture, I considered the causes of suppurative inflammation of the liver. I shall now speak of the morbid appearances produced by this form of inflammation, and of the symptoms to which it gives rise.

The earliest perceptible change in the texture of the liver from suppurative inflammation, is redness—a redness usually brighter than that of simple congestion—and softening.

This was the earliest change observed by Cruveilhier in his experiments of injecting mercury into the mesenteric veins of dogs. When the dogs died before sufficient time had elapsed for the formation of pus, the mercury was found disseminated through the liver, and each globule surrounded for a short distance by hepatic tissue of a bright red colour and softened. In the human subject, in almost all cases of abscess of the liver speedily fatal, the hepatic tissue about the abscess is of a bright red, and softened. This preliminary stage in which the substance of the liver is red and soft, is, however, often of very short duration. The inflammation soon passes, in some cases in a few days only, to suppuration and abscess. Dr. Stokes has noticed a stage, intermediate between red softening and abscess, and analogous to grey hepatitis, or purulent infiltration, of the lung, in which the hepatic tissue is soft and yellowish, and leaves a puriform exudation on the scalpel.

I have never found this change in the liver without abscess, nor does Dr. Stokes

seem to have done so. but in several instances I have observed it extending a distance of two or three lines about a recently formed abscess. This state of yellow softening or purulent infiltration is, therefore, very transitory, and we may consequently consider red softening and abscess as the anatomical characters of suppurative inflammation of the liver.

Abscesses of the liver vary extremely in size. In some instances they are no larger than peas, while in others they attain an extraordinary volume. In one instance I estimated the quantity of matter in an abscess of the liver at two quarts. A case is given by Annesley, in which an abscess in the liver contained ninety ounces of matter; and one still more extraordinary is mentioned by Portal, in which the matter was estimated at the incredible quantity of twelve pints. These large abscesses seem, in most cases, to be formed by the union of smaller ones.

The matter in an hepatic abscess is white or yellowish, and precisely like the pus of a phlegmon. It is free from odour, unless it be in close proximity to the lung, when it sometimes becomes decomposed and foetid, perhaps from permeation of air.

Many of the old writers describe the pus in abscess of the liver as being of a red or claret colour; but this description is incorrect. In all the abscesses of the liver that I have examined the pus was precisely like that of a phlegmon. The error of the writers who have described it as being reddish, resulted, I imagine, from their having met with a case in which the abscess opened into the lung, and in which the pus, in its passage through the lung, became mixed with blood and broken down pulmonary tissue. They described the matter *expectorated*, and not the matter contained in the abscess. It is not very uncommon for an abscess of the liver to open into the lung. I have met with several instances of the kind, and in all of them the matter expectorated was of a dirty-red, or

brownish, pus. The colour was acquired in its passage through the lung. The matter in the abscess was yellowish or white.

In cases that prove speedily fatal, we find the abscess bounded simply by red and softened hepatic tissue; but in others, it is lined by a false membrane or cyst. The structure of the cyst varies very much in different cases,—depending in some degree, perhaps, on the general condition of the patient, but chiefly on the date of the abscess and on its size. In small abscesses, and in abscesses recently formed, the pus is surrounded by a layer of albuminous matter, a line or two in thickness, resembling concrete pus, and beyond this the hepatic tissue has its natural texture; while in old abscesses of large size the cavity is bounded by a dense grey substance, like cartilage, three or four lines in thickness, and the hepatic tissue, for a line or two even beyond this, is pale and condensed, obviously in consequence of pressure.

The following seems to be the mode in which these cysts are produced. At first, the pus becomes bounded by a layer of concrete albuminous matter. The abscess then acts as a foreign body, causing pressure on the surrounding parts, and an inflammatory action which leads to the effusion of fibrine. The fibrine, becoming organized, forms the cartilaginous layer I have described.

An abscess once formed in the substance of the liver may have various issues. The abscess may burst into the cavity of the peritoneum, causing inflammation of that membrane, which proves rapidly fatal. But this seldom happens. In a great majority of instances, when the matter gets near the surface of the liver, adhesive inflammation is set up in the portion of peritoneum immediately above it, and lymph is poured out, which glues the liver to adjacent organs—the abdominal parietes, the diaphragm, the stomach, the duodenum, the colon, according to the seat of the abscess—and the matter is discharged, not into the cavity of the peritoneum, but outwards, or into the lung or pleura, or the different portions of the intestinal canal just specified.

But the abscess admits of another termination—the pus may be absorbed or discharged through the gall-ducts, the cavity of the abscess contract, and its place be marked by a dense stellar cicatrice.

M. Louis, in a paper he published some years ago on abscess of the liver, states that he has never met with cicatrices in the liver, and seems to doubt the curability of an hepatic abscess in this way. If he had consulted the splendid work of Annesley, his doubts would have been removed. He would there have seen more than one plate exhibiting cicatrices of the liver, the consequence of abscess. I have frequently ob-

served the capsule drawn in and puckered over an hepatic abscess—no doubt, from partial absorption, or discharge, of its contents; and I have in several instances found the capsule so drawn in and puckered over a stellar cicatrice—but only in one instance have I had an opportunity of observing in the same subject the different stages of the process. This was in the person of my late colleague, Mr. Lawson, consulting surgeon to the Dreadnought, who died two years ago, of Bright's dropsy.

In early life he had been much in India, but returned twelve years ago, and was soon after appointed resident surgeon to the Dreadnought. He continued in this office several years, and then settled in the city. His health, if not good, rarely caused interruption of his business. He had a strong impression that he had some disease of the liver, but few of his medical friends thought so. He had no pain in the side, and his complexion was remarkably clear.

The examination was made by Mr. Busk, in presence of Dr. Bright and myself. The liver had no unnatural adhesions, and presented no traces of inflammation of the capsule, but was deformed by deep fissures across its surface. On cutting across these fissures, we opened small abscesses lined by a thin false membrane. There were a great number of these abscesses, but they were all small: not one was larger than a filbert. In a few places, instead of an abscess, we found a small stellar cicatrice, of white, cartilaginous, substance.

The capsule and the peritoneum covering the liver had undergone no change of structure. They were merely drawn in by the contraction of internal parts. The fissures on the surface were not cicatrices, but the effect of cicatrices situated deeper in the hepatic tissue.

As Mr. Lawson had no acute affection of the liver after his return from India, the abscesses must have been of more than ten years' standing.

Abscesses are found in livers of every shade of colour that can be produced by variation in the quantity of blood and in the quantity and quality of the bile. In one case I found the organ of a pale fawn colour; in another, of a dark olive. In subjects dead of chronic dysentery, the liver is usually pale, from its containing but a small quantity of blood.

Livers in which we find abscesses are seldom indurated from interstitial deposit and organization of coagulable lymph. The inflammation which terminates in abscess, and that which leads to the effusion of coagulable lymph and induration, or *cirrhose*, are not different in degree merely, but in *kind* also. Abscesses are never found in the *hob-nail* livers of the gin-drinking popu-

lation of our large towns; and it happens seldom, and then I believe only by coincidence, that there is much induration in the livers of persons who return from India with abscess.

It is now time that I should speak of the symptoms of suppurative inflammation of the liver.

In most works on medicine these have been described as being much more uniform than they really are. A picturesque group is sketched, which it seems very easy to identify; but in actual practice it is far otherwise. The physicians who have had most experience in this disease confess their inability, in many cases, to distinguish it from other diseases of the liver, and in some cases even to pronounce that the liver is the seat of disease at all. Here, as in the diseases of other internal organs, our diagnosis will be much aided by knowledge of the circumstances under which the disease arises. This knowledge will make us observant of symptoms which would otherwise escape our notice, and will enable us to interpret them rightly.

The symptoms are most obvious, and most in accordance with the descriptions usually given, when the inflammation is caused by a blow, or some direct injury from without. The injury is usually done to the convex surface of the liver, and the local symptoms are well marked. There is pain and tenderness in the region of the liver, and a sense of fulness and resistance under the false ribs from increased size of the organ. The liver becomes enlarged, and if the abdomen be flaccid and the intestines empty, its edge can be felt some inches below its natural limit. The secretion of bile may be suppressed or deficient, and the patient jaundiced.

In addition to these symptoms, which may be called *special*, from their pointing to the liver as the seat of disease, there soon appear, as in simple inflammation of other organs, the general symptoms of inflammatory fever: the pulse is frequent and full; the skin hot; the tongue furred and yellowish; the appetite gone, or much diminished; the patient is thirsty, and there is occasionally vomiting of bilious matter.

These general symptoms, together with the special symptoms—pain and tension in the region of the liver, and jaundice—occurring after an injury to the side, are perhaps, in the absence of evidence of disease of the lung or pleura, sufficient to characterise suppurative inflammation of the liver.

But, as I have before remarked, the liver is so well shielded by the ribs, that the disease is seldom caused in this way. It occurs much more frequently after surgical operations and injuries done to other parts of the body, from suppurative inflammation

of some vein, and the consequent contamination of the blood by pus.

In such cases the general symptoms do not aid our diagnosis. There is already high fever, which rapidly assumes a typhoid character—the consequence of the contamination of the whole mass of blood, and of the various local inflammations to which this gives rise.

We can only infer that abscesses are forming in the liver by the occurrence of special symptoms—pain in the region of the liver, and jaundice—in the midst of the general disorder. But these special symptoms do not exist in all cases. There may be no jaundice; and pain even may be wanting; or the typhoid state into which the patient falls may prevent his distinctly perceiving or expressing it. In such cases the abscesses in the liver can be discovered only after the death of the patient.

In the same way, when inflammation of the liver occurs during the acute stage of dysentery, or on a recurrence of acute symptoms in chronic dysentery, the general symptoms do not aid us in discovering it, because they are fairly attributable to the primary disease. Our diagnosis must be founded on local symptoms chiefly—pain and tenderness referrible to the liver, tension in the right hypochondrium, and jaundice. Our knowledge of the connection between the two diseases enables us to attach due importance to these symptoms, and ascribe them to their actual cause. Pain and tenderness in the region of the liver, slight increase in its volume, and jaundice, which, in other circumstances, might excite little alarm, and be attributed to their most frequent cause—inflammation and obstruction of the gall-ducts—when they occur in the course of dysentery, will lead us to dread suppurative inflammation and abscess.

But these special symptoms are far from being all present in every case; and in some cases they are entirely wanting. In the autumn of 1839, I had a patient in the Dreadnought, who presented merely the symptoms of irritative fever. He was not jaundiced, and made no complaint of pain or tenderness. He died, and I found, what I did not at all expect, a recently formed abscess, containing more than a pint of matter, in the centre of the liver.

Andral, Abercrombie, and indeed all writers who have published a series of cases of suppurative inflammation of the liver, have noticed the same fact—that occasionally, in this disease, the patient has no symptoms immediately referrible to the liver, and presents merely the signs of continuous fever.

Annesley says, "The supervention of abscess of the liver (in dysentery) is often not manifested by symptoms of a decided

nature." "The formation of matter may commence and terminate without the appearance of any of those signs on which the inexperienced are taught to rely." In another place he says, "When the disorders of both viscera are nearly coeval, the inexperienced observer may not detect the presence of biliary derangement until the disease is hastening to a fatal termination, and unequivocal signs of abscess are present. In cases of this description, the violence of the dysenteric symptoms absorbs the whole attention of both patient and practitioner, and the complication is overlooked."

The presence or absence of the symptoms directly referrible to the liver depends chiefly on the *situation* and *extent* of the part of the liver inflamed. These symptoms are, as I have said, fulness of the right hypochondrium, from enlargement of the liver; pain or tenderness; and jaundice.

The degree of enlargement must evidently depend, in some measure, on the *extent* of the part inflamed. If only a small portion of the liver be inflamed, the inflammation, though attended with considerable distension of vessels, may run through all its stages without producing any enlargement of the organ discoverable by touch. But in this kind of inflammation there is seldom, I believe, much increase of volume even of the part inflamed. Enlargement of the liver is much more common in adhesive inflammation; that is, in inflammation which terminates in effusion of coagulable lymph, and causes chronic induration, or cirrhose. This kind of inflammation, at least when produced by spirit-drinking, usually involves the entire organ, and, apparently by causing an interstitial deposit of lymph, often much increases its size; while suppurative inflammation is, as we have seen, generally limited to a small part of it; and before pus is formed even this part may be little, perhaps not at all, increased in volume.

The circumstance that suppurative inflammation is generally partial, serves also to explain the occasional absence of *jaundice*. A portion only of the liver is inflamed; and as any part can perform its function independently of the rest, the sound parts may be adequate to free the blood of the principles of the bile.

The presence or absence of *pain* seems to depend, not so much on the *extent*, as on the *situation*, of the portion inflamed. As long as the inflammation is confined to deep-seated parts, and is not sufficiently extensive, or attended with sufficient congestion, to cause much enlargement of the liver and stretching of its capsule, there is little or no pain. The substance of the liver, like that of the lungs and other parenchymatous organs, is little susceptible of pain. The sharp and severe pain that fre-

quently attends inflammation of them has its seat in their fibrous or serous covering.

The occasional absence of symptoms directly referrible to the liver is not, then, so inexplicable as might at first appear. It is satisfactorily accounted for by the circumstance, which dissection has already disclosed to us—that suppurative inflammation is generally partial, and often involves only the *substance* of the liver, whose natural sensibility is slight.

When inflammation of this character involves all the secreting substance of the liver, there is deep jaundice, and the patient dies from oppression of the functions of the brain. A case, which seems to have been one of this kind, is given by Andral.

When an abscess in the liver has become encysted, if small and deep-seated, it causes little constitutional disturbance, and may give rise to no symptoms by which its presence can be discovered. I have already mentioned the case of the late surgeon to the Dreadnought, who, for ten years before his death, had his liver studded with abscesses, but was still competent to all the duties of his profession. I have no doubt that many of the old East Indians, who have suffered from dysentery, and who return to this country with sallow countenances and impaired health, are labouring under abscess of the liver.

But besides the general symptoms of fever, and the special symptoms—pain and tension in the right hypochondrium, and jaundice—which occur in well-marked cases of suppurative inflammation of the liver, and which, in conjunction with the circumstances in which suppurative inflammation is known to arise, are perhaps sufficient to characterise it, there are some other symptoms occasionally observed, which cannot be referred to either of the preceding heads, and which frequently continue after the feverish symptoms are past. These symptoms are, pain in the right shoulder; vomiting; a short, dry cough; and permanent rigidity of the muscles of the abdominal parietes, but especially of the right rectus muscle.

Pain in the right shoulder has long been noticed, indeed from the time of Hippocrates, as an occasional attendant on hepatic disease; and considerable importance has been attached to it as a sign of hepatic abscess. M. Louis, in his paper on Abscess of the Liver, states that none of his patients (they were five in number) had any pain in the shoulder; and he hesitates to believe that this symptom is really referrible to disease of the liver. He conjectures that, when present, it may depend on concomitant disease of the lung or pleura. Nearly the same opinion has been expressed by M. Andral.

Pain in the right shoulder is, indeed, far

less frequent in cases of abscess of the liver than is generally imagined; but it existed in five of the fifteen fatal cases I had to treat at the Dreadnought, and in some of these cases there could be no doubt that the pain in the shoulder was dependent on the disease of the liver.

In the first of these five cases (case 5 of the table), there was a small abscess on the convex surface of the right lobe, and the peritoneum covering the abscess adhered, for the space of a shilling, to the reflected layer of peritoneum. There were some old adhesions of the lung to the pleura costalis, but no trace of recent pleurisy. Both lungs were pale and perfectly healthy.

In another of these cases (case 8 of the table), in which the abscess was on the convex surface of the liver, and formed a prominent tumor, the pain of the shoulder was so severe as to cause the patient to moan. The pain continued extremely severe for a long time, and at length was relieved on our opening the abscess.

In a third case (case 9 of the table), where the abscess likewise formed a prominent tumor, the patient complained of an aching pain in the right shoulder, extending to the right scapula, and up the right side of the neck.

In a fourth case (case 12 of the table), the pain in the shoulder varied in intensity with the pain in the right side. When the side was easy, the shoulder was easy also. The two pains were evidently related. In this case there were five or six abscesses of various sizes in the liver—one opened into the lung, another was on the convex surface of the right lobe.

In the fifth case the abscess was likewise on the convex surface of the right lobe. There was no recent inflammation of the lung or pleura.

In two or three of these cases the pain in the right shoulder continued for months, and in all of them it was associated with pain in the situation of the abscess.

In all the cases the abscess was on the convex surface of the right lobe, and adhesions had formed between the peritoneum covering the abscess, and the layer of the peritoneum reflected over the diaphragm or abdominal parietes.

These cases tend to bear out a statement made by Annesley, that pain of the right shoulder, when present, is a sure indication that the disease is in the right lobe, and they explain how it happened that pain in the right shoulder was supposed to be so much more frequently associated with abscess of the liver than it really is. Pain in the right shoulder occurs chiefly, if not exclusively, in those cases in which the abscess is situated on the convex surface of the right lobe. Now, before the cultivation of morbid ana-

tomy, it was only when the abscess was so situated, and when it formed a prominent tumor, that its existence was recognised. The ancients, therefore, observed pain in the shoulder in a great proportion of the cases in which they discovered the existence of hepatic abscess; whereas the frequent dissections of late years have taught us that abscess is more frequently seated deep in the substance of the liver than on its surface, and that pain of the right shoulder is more frequently absent than present.

The pain is usually described as a gnawing, aching pain, about the top of the shoulder. There is no swelling or redness of the shoulder, and the pain is not much increased by pressure on it—sometimes, indeed, the pain is relieved by holding or pressing the shoulder—but it is often much increased by pressure on the liver. The pain is, in fact, as it has always been represented to be, a *sympathetic* pain, like the pain of the knee from disease of the hip.

The cough and vomiting are of the same kind. Irritation of the liver, like irritation of the stomach, produces a short, dry, sympathetic cough; and, like irritation of most of the abdominal viscera, it may occasion vomiting.

M. Louis has not only thrown discredit on pain of the shoulder as a symptom of hepatic abscess, but has advanced similar opinions respecting the vomiting and cough. The *vomiting* he supposes to arise from inflammation of the mucous membrane of the stomach; and the *cough* to be the consequence of bronchitis. With respect to the cough M. Andral has concurred in the opinion of M. Louis.

I have had several opportunities of satisfying myself that the opinion of these eminent pathologists is incorrect; and that the cough and vomiting, so frequently observed in abscess of the liver, do not depend on any affection of the lungs or stomach, but that they are what I have stated them to be, sympathetic affections solely dependent on irritation of the liver.

In the autumn of 1837, a young man (case 4 in the table), was admitted into the Dreadnought, immediately on his arrival from Calcutta. He was much emaciated, and stated that he had been ill thirty days of fever, and that during the last ten days he had vomited everything he had taken. His belly was much drawn in, and the parietes were extremely rigid, but there was no tenderness on pressure. He was somewhat thirsty, but afraid to drink, on account of the vomiting it immediately excited. My impression was that his complaint was gastritis, and I prescribed for him accordingly. The symptoms increased, and at the end of a fortnight I could get him to take little besides toast and water, which he

sipped rather than drank. He died about a month after his admission to the Dreadnought. The stomach was found apparently healthy, but the liver was the seat of an enormous abscess.

In this case, I have mentioned that the abdominal parietes were in a constant state of rigidity; without pain or tenderness. I remarked the same symptom in several of the other cases. In one of them (case 9 of the table), it was very striking; the abdominal parietes were hard and boardy, especially on the right side, with the skin loose over them.

From an article in a recent number of the British and Foreign Medical Review, I find this symptom was noticed by the late Mr. Twining, and some other surgeons in India, and considered as one of the surest indications of deep-seated abscess of the liver. Like the other symptoms with which I have associated it, it is a purely sympathetic affection. It is met with in other diseases besides abscess of the liver. I found it in a very striking degree in a man who had cancerous ulceration of the stomach, eating into the liver, to which the stomach adhered.

These sympathetic affections—the pain in the right shoulder, the vomiting, the cough, the rigidity of the abdominal muscles—are of little value in the early stage of suppurative inflammation, because they are then of more doubtful import, and are in some degree masked by the general symptoms of fever; but when they exist after the acute stage has passed and the fever has subsided, and present the characters I have noticed—when the pain is seated about the top of the shoulder, is unattended by redness or swelling, and is not much increased by pressure on the shoulder, but by pressure on the side—when the cough is short and dry, and cannot be explained by the condition of the lung—when the vomiting occurs immediately after food or drink has been taken (which is a general character of sympathetic vomiting)—when, in fact, these symptoms have the characters of sympathetic affections, they are strong indications of the existence of an hepatic abscess.

The symptoms I have enumerated are almost the only symptoms of suppurative inflammation of the liver, or of its termination—abscess—while the abscess is confined to the substance of the organ.

But when the abscess is large, and near the surface, it may, according to its situation, discharge itself in various ways. If situated on the outer surface of the liver, it may either burst into the cavity of the peritoneum, or, by means of adhesions, make its way through the abdominal parietes; if it be situated on the upper part of the liver, in contact with the diaphragm, it may perforate the diaphragm and burst into the cavity of

the pleura, or adhesions may form between the lung and the portion of diaphragm covering the abscess, and the abscess may open into the lung and be discharged through the bronchial tubes; if the abscess be near the edge, or on the under surface of the liver, adhesions may form between the peritoneum covering it and the stomach, duodenum, or large intestine, and the matter be discharged through the intestinal canal.

There will, of course, be a variety of symptoms indicative of these several results.

If the abscess burst into the cavity of the peritoneum, there will be sudden accession of pain, vomiting, and all the symptoms of peritonitis from perforation. The patient will speedily fall into collapse, and survive at most a few days.

If, however, the matter discharge by oozing merely, it may not become diffused over the surface of the peritoneum, to excite general peritonitis. It will spread over the liver, and will be limited by adhesions, so as to form a circumscribed abscess in the cavity of the peritoneum. This mode of termination is noticed by Cruveilhier, and happened in two of the cases I treated at the Dreadnought.

If the abscess open into the stomach, there will be sudden vomiting of purulent matter; if into the intestines, sudden diarrhoea, with discharge of pus; and, in either case, the occurrence of these symptoms will be attended by subsidence of the tumor, if any exist.

If the abscess perforate the diaphragm, it may open into the cavity of the pleura, and excite suppurative pleurisy; but this rarely happens. In almost all cases in which the abscess is working its way through the diaphragm, it excites inflammation of the pleura immediately above it, and adhesion, which is sometimes singularly limited, takes place between the diaphragm and the lung. The abscess then opens into the lung, and the matter is discharged through the bronchial tubes. When this happens, it is marked by very characteristic symptoms—by a new train of stethoscopic phenomena, which I need not stay to notice, and by the sudden expectoration of a dirty-red, or brownish, puriform matter. I have already noticed this colour, which arises from the pus in its passage through the lung becoming mixed with blood and broken-down pulmonary tissue. There is no expectoration like it in any disease of the lung itself, and I believe that its appearing is pathognomic of abscess of the liver, or at least of abscess perforating the lung. I observed it in several instances in the Dreadnought, and more than once was led by it to detect an abscess in the liver, of which I had previously no suspicion. When the abscess is large, this matter may continue to be spit up for a great length of

time. It generally comes up very easily, in some cases by mouthfuls, almost without effort on the part of the patient.

When an abscess of the liver opens into the intestines, or into the lung, all the matter may be discharged, the cavity may close up, and the patient recover. I have met with one instance in which a patient, who had all the symptoms of abscess of the liver discharging through the lung, so far recovered that he left the hospital apparently well. But such a happy result is very rare, and happens, I imagine, only when the abscess is small, or recently formed. In the majority of cases the patient dies, exhausted by protracted suppuration and hectic.

The protracted suppuration depends on the walls of the abscess being firm and unyielding. The hepatic tissue, and the hard gristly substance that always surrounds an old abscess of large size, cannot contract so as to close the cavity, which must consequently continue to be filled with pus. The case is analogous to those cases of old empyema in which the lung is condensed and irrecoverably bound down against the vertebral column. In such cases, the fluid, if serous, continues to be absorbed as long as the contraction of the ribs, the encroachment of the opposite lung, the dilatation even of the bronchial tubes of the compressed lung, continue to diminish the cavity of the affected side; but when all these means have attained their limit, and the cavity can be no farther diminished, an end is put to the absorption of the fluid. It is a physical impossibility that a drop more of the fluid can be absorbed. In the same way, in old abscesses in the liver, if the hardened tissue about the abscess cannot contract so as to close the cavity, the cavity must continue to be filled by pus.

It is, then, to the unyielding nature of the walls of the cavity that we must ascribe the protracted suppuration and the fatality of hepatic abscess, even in cases in which the free discharge of the pus would seem to promise a favourable issue. The fatality has no relation to the outlet by which the matter is discharged. I have met with several cases in which the abscess opened through the abdominal parietes, and all of them proved fatal; so that it seems doubtful whether such an opening is more favourable than one into the intestine or lung.

The abscess, if large, may discharge through more outlets than one. In one of the cases I treated at the Dreadnought, the abscess discharged first through the lung, and afterwards through the abdominal parietes also. The reason of this is, that from the sides of the cavity not collapsing, the abscess is not emptied through the first opening.

The treatment of suppurative inflammation

of the liver is very unsatisfactory. I shall detain you only to make a few remarks on two points connected with it.

The first is the abuse of mercury.

It has been well observed by Abercrombie—"In the liver diseases of this country mercury is often used in an indiscriminate manner, and with very undefined notions as to a certain specific influence which it is supposed to exert over all the morbid conditions of this organ. If the liver be supposed to be in a state of torpor, mercury is given to excite it; if in a state of acute inflammation, mercury is given to moderate the inflammation and reduce its action."

This vague and indiscriminate use of mercury has resulted from its unquestionable efficacy in some derangements of the liver, and from the difficulty of distinguishing the different disorders of this organ. In doubt as to the real nature of the malady, the physician is naturally anxious to give his patient the chance of a remedy that occasionally produces strikingly beneficial results; and often, in so doing, aggravates the disorder it is his object to relieve.

This misapplication of mercury will continue until the diagnosis of the diseases and derangements of the liver is more sure, and physicians have ascertained those in which mercury has a curative influence. There can be no doubt that much of our uncertainty as to the action of medicines depends on our calling by the same name, and treating in the same manner, diseases that arise from different causes, and are essentially different in their nature.

It seems to me that mercury is peculiarly unsuited to the disease we have been considering—suppurative inflammation of the liver.

One objection to its employment in this disease is the short time allowed for its action. When the inflammation is excited by the presence of pus in the blood, and in all probability when it occurs in the course of dysentery, it passes on to suppuration in two or three days; and when suppuration has taken place, and abscess formed, it is agreed by all that mercury not only does no good, but the singular fact seems established, that in whatever quantity we give it, it fails to produce its usual constitutional effects. Annesley says, "There can be no doubt that the system will not be brought under the full operation of mercury, or that pytalism will not follow on the most energetic employment of this substance, when abscess exists."

He repeats this opinion again and again, and even considered resistance to the action of mercury as a proof that abscess had formed in the liver. It is only, then, before suppuration has taken place that mercury can have any beneficial influence, and during this time the system, from the presence of

high fever, is little disposed to be affected by it.

The next point I have to say a few words on is the danger of opening abscesses of the liver.

One source of danger noticed by Annesley, Dr. Stokes, and many other writers, arises from the difficulty of diagnosis of an hepatic abscess, and our liability to mistake a distended gall-bladder for it. Such a mistake is almost immediately fatal to the patient. A distended gall-bladder is seldom adherent to the abdominal parietes, and if it be punctured, the bile escapes into the cavity of the peritoneum, the patient is seized with vomiting, falls rapidly into collapse, and generally dies at the end of a few hours. Two cases of this kind are alluded to by Dr. Stokes in the 5th vol. of the Dublin Hospital Reports, and many others are on record. This source of danger may, however, be avoided by attention to the situation and character of the tumor. The tumor formed by a distended gall-bladder is globular, and circumscribed, and hard, and equally resisting in every part, while the tumor from abscess is more diffused, and is soft and fluctuating at its summit, while its base is hard and resisting.

A source of far greater danger is the circumstance I noticed when speaking of the morbid anatomy of abscess of the liver—namely, that the inflammation which leads to abscess is often confined to the substance of the organ, and does not involve its capsule. As the abscess approaches the surface, adhesive inflammation of the peritoneum immediately above it often takes place, and a small quantity of lymph is poured out, which causes adhesion between the wall of the abscess and the parts with which it is brought into contact. These adhesions are often singularly limited. Sometimes they do not form at all, and, as I have before remarked, the abscess bursts into the cavity of the peritoneum, causing speedy collapse and death. By opening an abscess of the liver before adhesions have formed, we are directly instrumental in bringing on this fatal issue; the pus escapes into the sac of the peritoneum, and the patient dies in a few hours, obviously from the effects of the operation.

I would, then, never recommend opening an abscess of the liver until I was assured, by a circumscribed oedema, or a slight blush on the skin, that union had taken place between the integument and abscess. When these signs are wanting, and the skin has its natural appearance and colour, we can never be sure that adhesions have formed, and if we thrust a knife into the abscess, we run the risk of discharging the matter into the cavity of the peritoneum.

Dr. Graves has ingeniously recommended

a mode of proceeding by which he supposes this danger may be obviated. It is, not to open the tumor at once, but to make an incision across the most prominent part of it through the abdominal muscles, so as to reach the peritoneum without dividing it, and to fill up the wound with a pledget of lint. The object of this is to excite circumscribed inflammation of the peritoneum which may produce adhesion between the reflected layer of the peritoneum and the layer covering the abscess. The abscess is then allowed to open of itself. I have seen this operation performed twice, but with very unsatisfactory results. There is, indeed, a third source of danger, which has not been noticed by the writers to whom I have referred, but which is, I think, more to be dreaded than those I have already mentioned. It is, that by the entrance of air into the wound, a fresh inflammation may be excited, which may lead to gangrene, and speedily carry off the patient. This circumstance happened in one of the cases I treated at the Dreadnought. (Table, case 6). An abscess that pointed outwardly was opened with considerable temporary relief to the pain which the patient suffered in the side and shoulder. But the discharge became fetid and dark, of the colour of coffee-grounds: the patient sunk and died at the end of a week. The walls of the abscess, and the hepatic tissue immediately around them, were found in a state of gangrene.

A similar case is related by Cruveilhier, in Liv. 40 of his *Anat. Pathologique*.

I have as yet spoken only of inflammation involving the secreting substance of the liver. There are other forms of suppurative inflammation of this organ, but they are much more rarely met with.

1. One of the most interesting of these is where suppurative inflammation is set up in the interior of an hydatid cyst, converting it into an abscess. This, considering the rareness of hydatids in the liver, is not of unfrequent occurrence. I have met with one instance of it. Three are recorded by Andral, and two or three by Cruveilhier. The fragments of hydatids were found floating in pus.

Cruveilhier has made the important remark, that while the fluid in hydatid cysts in their *healthy* state, if one may be allowed the expression, is always limpid and colourless, yet in all those he examined which had been converted into an abscess, the pus had an orange, or greenish, hue. He believes that this colour is due to the presence of bile; and that the entrance of bile into the cyst is the most common cause of the suppurative inflammation that transforms it into an abscess. I have little doubt that this explanation applies to the majority of such cases, but we must also admit that suppu-

tive inflammation of the cyst may be excited in other ways. In one of the cases given by Andral, the pus was quite white.

2. Another form of suppurative inflammation of the liver is, where the pus is not collected into a circumscribed abscess, but diffused through the cellular tissue that surrounds the portal vein and the accompanying artery and duct.

Cruveilhier mentions the case of a man who died of gangrenous inflammation of the cellular tissue of the pelvis, the consequence of extravasation of urine. He found pus in the liver, not collected into an abscess, but diffused through the cellular tissue that enters into the portal canals. The most probable explanation of this is, that the urine was absorbed, conveyed to the liver, and some of its principles extravasated in the cellular tissue in the portal canals.

I have said that in ordinary cases of abscess of the liver, the gall-bladder, and ducts, and capsule, are seldom affected, excepting secondarily; and I assigned as a probable reason for this, that suppurative inflammation of the liver is usually caused by some contamination of the portal blood, which is not distributed to these parts.

3. Suppurative inflammation may, however, occur in the gall-bladder or excreting ducts, or in the capsule, *primarily*, and with similar disease of the secreting substance of the liver.

Numerous instances are recorded of suppurative inflammation of the mucous membrane of the gall-bladder, from the irritation of calculi, or otherwise, and some instances where, from closure of the cystic duct, the gall-bladder was converted into an abscess.

A case is given by Cruveilhier, in which the extremities of the gall-ducts were dilated into small cavities containing puriform mucus; the consequence, it would seem, of obstruction of the hepatic duct by a gall-stone.

4. There is still another variety of suppurative inflammation of the liver; namely, suppurative inflammation of the capsule, or of the peritoneum covering it. This may take place without suppurative inflammation of the secreting substance of the liver, and at first, without inflammation of the rest of the peritoneum. But when pus has formed on the surface of the liver, it becomes diffused over the surface of the peritoneum, and causes general and rapidly fatal peritonitis, just as when discharged by the bursting of an abscess. A case of this kind is given by Andral. (Clin. Méd. iv. 310). The liver was of its natural size, but its tissue much softened. It would seem that in such cases the material cause of the inflammation, if such exist, is conveyed by the arterial blood.

CLINICAL REPORT OF CASES

TREATED AT THE GLASGOW EYE INFIRMARY.

BY WILLIAM MACKENZIE, M.D.

Second stage of glaucoma affecting each crystalline lens—Slow advance of the disease—In right eye combined with incomplete amaurosis—In left uncombined—Lenses divided and absorbed—Recovery of good vision in left eye—Remarks on the several stages of glaucoma.

Case.—No. 10804, January 14th, 1841.—Robert Shaw, a weaver, aged 56. Lenticular opacity in each eye, of a pale muddy greenish hue, confined apparently to the central and posterior portions of the lenses. Vision of right eye, in which the opaque appearance is most advanced, so much impaired, that he cannot distinguish objects with it. Vision of left eye also imperfect, but with it can still distinguish the fingers. Pupils of natural size; their motions limited and sluggish. Eyeballs of natural consistence; deep set in orbits. Sight began to fail four or five years ago, after having had typhus fever, followed by erysipelas. Has never been myopic nor presbyopic, as far as he knows.

Extr. Belladon. ad palpebr.

15th.—Since the application of the belladonna, thinks his vision less distinct.

21st.—Pil. Subm. Hydr. ter ind.

Feb. 1st.—With left eye can discern a character an inch long. Right eye almost insensible, except to light and shade. Opacity of lenses so far advanced that no inverted image is visible, on examining eyes catoptrically.—Omit. Pil.

10th.—Vesicat. parv. ad tempora.

15th.—Thinks his vision declining.

19th.—Sol. Iodid. Ferr. gtt. x.; ter ind. ex cyath. aq.

29th.—Vomits the drops.—Omit. Med.

May 4th.—Pupils again dilated by belladonna. Vision slightly improved.

A blue belladonnam.

9th.—Vin. Antim. gtt. x. ter ind.

June 15th.—Is troubled with catarrhal ophthalmia.

Ung. Pr. Rub. et Collyr. com.

July 8th.—Pupils again dilated by belladonna. Vision worse.

9th.—Pil. Calomel. et Op. i. o. n.

Aug. 4.—Omit. Pil.—Utatur Velamine.

Oct. 5th.—Ung. Pr. Rub. o. n.

Nov. 22d.—Collyr. c. Vin. Bellad.

Jan. 23, 1842.—Slight catarrhal ophthalmia of both eyes.

Cont. Ung. et Collyr.

Sept. 12th. — Opacity, still of the same muddy green colour, has slowly advanced towards the iris. Has been till lately engaged as a letter of houses, but cannot see to continue this employment.

28th. — Right pupil being dilated by belladonna, curved needle introduced through sclerotica, and anterior capsule divided.

29th. — An attack of pain last night, for which he was bled, and had a calomel and opium pill.

Extr. Bellad. ad palp. dextr. — Linteolum aq. frig. madefactum super ocul. dextr.

— Cont. Pil. m. et. v.

Oct. 1st. — Omit. Pil.

Nov. 6th. — Curved needle again introduced through right sclerotica, and capsule and lens divided.

7th. — Was bled this morning, on account of pain in right eye, and had four grains of calomel and one grain of opium.

Sumat Sulph. Magnes. ʒj.

17th. — A very fine straight needle introduced through left sclerotica, with the view of displacing the lens, in the mode recommended by Mr. Morgan, in Guy's Hospital Reports, Vol. vii. p. 461. This not being effected, the anterior capsule was divided, and the needle withdrawn.

Extr. Bellad. ad Palp. Sinistr.

29th. — Pil. Hydr. o. n.

Dec. 3d. — Omit. Pil.

10th. — Division of left capsule repeated with curved needle passed through sclerotica, and the comminution extended partly to the lens.

25th. — Omit. Bellad.

Sulph. Quin. gr. j. ter ind.

Feb. 2d, 1843. — Left pupil being previously dilated by belladonna, capsule and lens again divided with curved needle passed through sclerotica.

Extr. Bellad. — Omit. alia.

14th. — Vision does not improve.

Vesic. pone aures.

May 16th. — Vision much improved since last report.

Aug. 1st. — Left pupil perfectly clear, and vision of this eye good; lower-outer part of right pupil clear; its upper-inner part occupied by an opaque capsular shred. With a $2\frac{1}{2}$ inch convex glass, reads a school testament, with left eye. With right eye, sees a little, when he looks dextrad.

Remarks. — Glaucoma is so called from the greenish appearance which it presents behind the pupil. It is a reflection of the light which has entered the eye, by the central and posterior laminae of the crystalline lens, arising from these laminae having lost their natural colour and consistence, and acquired an amber or reddish-brown hue,

with an abnormal degree of hardness and dryness.

The history of pathology sufficiently shows that dissection is the only way of discovering the nature of such diseases as cataract or glaucoma. If a cataractous lens is extracted from the eye of a person of 50 or 60 years of age, its superficial laminae are found to be of an opaque whitish appearance, like half-boiled white of egg, while the rest of the lens is of an amber colour, and rather less opaque than the surface. If a glaucomatous lens is extracted, its superficial laminae are found to be comparatively transparent, and the departure from the normal state to affect chiefly its central portion. Viewed entire, by transmitted light, it appears more or less amber-coloured throughout. Divided by a section perpendicular to its surfaces, the kernel, and laminae immediately behind the kernel, are found to be of a reddish-brown colour, in a considerable degree opaque, hard, and drier than the superficial laminae. The lens, so changed, appeared while in the eye, and viewed therefore by reflected light, to be of a muddy green colour, but this was in a great measure an optical deception; for, taken out of the eye, all greenness is gone, both within the eye deprived of its crystalline, and in the lens under examination. The lens, then, in glaucoma, is in a certain sense dichromatic, like a bit of gold leaf; only that the latter viewed by reflected light is yellow, and green when viewed by transmitted light, whereas the glaucomatous crystalline is the reverse — green when seen within the eye by reflected light, and amber-coloured when seen by transmitted light out of the eye.

In its advanced stages, the disease styled glaucoma involves many other textures of the eye besides the lens, so much so, that Dr. Hays, the American editor of Mr. Lawrence's Treatise on the Eye, remarks, that "glaucoma cannot, strictly speaking, be considered as a disease; the term being applied to a group of symptoms which result from several and very distinct pathological conditions." I cannot see, however, that glaucoma is more objectionable in this respect than hundreds of other nosological terms. In an early stage, glaucoma is often limited to the lens, as it was in Shaw's left eye; or to the retina and lens, as it was in his right eye. It is sometimes the case, as in this individual, that the disease may continue for a number of years, without absolutely destroying vision, or becoming altogether irremediable.

The case of Shaw confirms two statements which I made respecting glaucoma in 1830; the one, that if the lens is removed by operation, the green appearance behind the pupil is lost; and the other, that the removal of a glaucomatous lens improves the vision

of the patient, unless, indeed, he be amaurotic*.

The term *glaucoma* comprehends a series of morbid changes, which in general develops itself slowly, in the course of years, and involves at last all the structures of the eye. I say "in general," for there is an *acute glaucoma*, in which many of the symptoms of the chronic variety are manifested often in a single night's time. The earliest and least important appearance of *chronic glaucoma* is merely a greenish hue, reflected from behind the pupil in the eyes of old people, but which is not necessarily connected with any material deterioration of vision, as is shown by the liveliness of the iris and the sensibility of the retina. A muddy green colour of the crystalline marks the *second* stage, as in Shaw; and along with this there is sluggishness of the pupil, and more or less obscurity of vision. The consistence of the eyeball is natural. This stage may last for five or six years, or more, vision declining by insensible degrees all the time. An unnatural hardness of the eye, with dilatation of the pupil, a varicose state of the external blood-vessels, and a still more marked loss of sight, are the signs of the *third* stage. In the *fourth*, the crystalline becomes cataractous as well as glaucomatous, opaque, that is to say, on its surface, as well as in its nucleus; it is also augmented in thickness, and pressed through the pupil, till at length it touches the cornea; the sclerótica is thinned, so as to allow the choroid to shine through it, and vision is totally extinguished. In the *fifth* stage, the cornea, pressed upon by the hypertrophied lens, inflames and gives way by ulceration, the lens escapes, and the internal vessels of the eye burst, and bleed through the ruptured cornea. A *sixth* stage presents the eye shrunk and atrophic.

These different stages of glaucoma run insensibly into each other. Although the disease is scarcely at any period of its course under the control of medical treatment, it is frequently arrested spontaneously in one or other of these stages, and makes no farther progress. In Shaw, it stopped, as it often does, in the second stage; the amber-coloured degeneration proceeding gradually towards the surface of the lens, but the other textures of the eye not becoming involved.

In the first and second stages, glaucoma is generally a disease of the crystalline alone. I say "generally," for sometimes amaurosis accompanies glaucoma from the very commencement. In its advanced stages, it presents symptoms depending on certain morbid conditions of almost all the textures

of the eye. The elements, in which glaucoma consists, when far advanced, reside in the lens, the vitreous humour, the retina, the choroid, the iris, the sclerótica, the blood-vessels of the eye, and even in the cornea. The order in which these different parts become affected is not invariably the same, nor the proportions in which they take part in this complex disease.

It is only in the early stages of glaucoma that the catoptrical examination of the eye is of importance. In the first stage, both the deep erect image formed by the anterior capsule of the lens, and the inverted image formed by the posterior capsule, are distinct. Both the images are rather larger than in the healthy eye, and both of them are of a yellowish hue. In the second and third stages the erect image is still larger than it was in its first stage, but its outline is indistinct, so that it appears as a diffused blaze. In the second and third stages, the inverted image is seen for a time, if, by moving the candle to one or other side, it is formed near the edge of the lens, but it appears less and less distinct as it is made to approach the centre of the pupil. At last, as the disease advances, it disappears entirely.

The second stage of glaucoma is the only one in which the removal of the lens is a practice which can be defended. The pale muddy green opacity behind the pupil, more deeply seated than the opacity in ordinary cataract; so that, owing to the transparency of the superficial laminae of the lens, the iris throws a broader shadow on the opacity than when the surface of the lens is affected; the consistence of the eyeball natural; the iris healthy in texture; the pupil not dilated; no inverted image, while the deep erect image forms a large yellow blaze; vision such as accompanies lenticular cataract; the progress of the disease much slower than that of lenticular cataract, occupying perhaps five or six years, whereas the formation of common cataract is generally effected within as many months; these are circumstances which enable us to pronounce the disease to be lenticular glaucoma in the second stage, and vision likely to be restored by the removal of the lens. This is an important fact, because practitioners are apt to conclude, when they see a green opacity behind the pupil, that the case is one of amaurosis, as well as of change in the refracting media of the eye. Hence patients are left as incurable, to whom the removal of the glaucomatous lens might restore vision. In the cases in question, a careful examination shows that vision is not extinguished, but that the eye retains nearly the same degree of sight as does a cataractous eye; the eyeball is not hard and stony to the feeling, as it is in the third stage, when, to a glaucomatous state of the

* Glasgow Medical Journal, vol. iii. p. 266. Glasgow, 1830.

lens, there is added a dissolution and an accumulation of vitreous humour; the sclerotic is not thinned, so as to allow the choroid to shine through; nor are the external vessels of the eye enlarged and varicose, as in the advanced and hopeless stages of the disease.

It sometimes happens, however, that incomplete amaurosis attends the second stage of glaucoma, as in Shaw's right eye, and then the operation proves fruitless.

In the third stage of glaucoma, the hope of doing any good by an operation is gone; and from the dissolved state of the vitreous humour and varicose condition of the vessels, there is much risk in attempting such a thing.

I have already hinted that the different elements of glaucoma do not present themselves in the same invariable order. The retinal, or amaurotic element, for example, is often the first to attract notice. Weller thinks that it is always the first in the series of morbid changes, for he says, "*Primum hujus morbi symptoma visus defectio est, pupillæ color subviridis multo serius demum animadvertitur**." But I believe it were more conformable to the fact to say, that in such instances as Weller has taken for the ground of this remark, an amaurotic eye has become glaucomatous, than that the group of symptoms which constitute glaucoma has originated in the retina.

Amaurosis so generally attends the advanced stages of glaucoma, that it has been presumed always, and in all stages, to do so. Mr. Wardrop even goes the length of calling glaucoma a species of amaurosis. "In some cases," says he, "the vitreous humour acquires a dull greenish colour, accompanied with insensibility of the retina, a species of amaurosis which has generally been called glaucoma†." Shaw's case shews the erroneousness of this view; his left eye was affected with distinct glaucoma, advanced into the second stage, yet the retina proved perfectly sensible.

It is scarcely necessary to remark, that the notion of glaucoma being an opacity of the vitreous humour is incorrect.

In its advanced stages, glaucoma is attended by dissolution of the hyaloid membrane. An inordinate quantity of vitreous fluid renders the eye preternaturally hard to the touch, and by pressure causes pain, photopsia, and destruction of vision. If the pressure is taken off, by puncturing the vitreous humour through the sclerotic, or even by evacuating the aqueous humour through a small opening in the cornea, a transient amelioration of vision, as well as

relief from the pain, is sometimes the result. But the aqueous humour, or the fluid which fills the place of the vitreous humour, being speedily regenerated, the pressure returns with its former effects.

The primary cause of glaucoma, from whence the whole series of symptoms springs, is unknown. Beer supposed it to be arthritic inflammation; Taylor a preternatural viscosity of the blood, and a cessation of the circulation through the vessels of the crystalline.

Taylor's notions regarding the seat and nature of glaucoma were much more correct than those of Brisseau, which so long prevailed. He understood it to be a diseased alteration of the crystalline, implicating its colour, transparency, and consistence, and ultimately combining with dilated pupil and amaurosis. He erred in supposing the capsule to be affected. His practice was to depress the lens and capsule, under the circumstances which I have enumerated as characterizing the second stage; or, to use his own words, "where the iris, and immediate organ of sight, maintain their healthful state*."

Operating, then, for the cure of glaucoma is not a new practice. Of late it has been revived in France by Dr. Sichel, who styles the second stage of glaucoma, as above described, *cataracte lenticulaire verte opérable†*.

It is necessary to be aware, that a glaucomatous eye is always very susceptible of suffering inflammation and disorganization, even from the slightest operation which may be practised upon it. Arthritic inflammation, with severe and long-continued pain, closure of the pupil, and total insensibility of the retina, is exceedingly apt to be the result of displacing a glaucomatous lens; while the operation of extraction exposes the eye almost as much to the danger of complete suppuration. Hence the propriety of having recourse rather to the operation of comminuting the centre of the anterior capsule by means of a fine curved needle passed through the sclerotic, and afterwards repeating a cautious division of the lens every six weeks till it is entirely absorbed. A cataractous eye is generally perfectly healthy, except that the lens, and especially its surface, has become opaque, but in every texture of a glaucomatous eye there is a lurking tendency to disease against which we cannot be too much on our guard.

MUSCLE A NEURO-MAGNETIC APPARATUS*.

(For the London Medical Gazette.)

THE active organs of locomotion, or the muscles, act by contracting or shortening the fibres of which they are composed, under an influence communicated to them, at the instance of the will, through certain nerves—nerves different in nature, you are to remember, from those which communicate between the organs of sense and the brain.

The mechanism by which muscles contract or shorten their fibres is a question which has been much agitated.

The view which I have been led to take is, that muscular fibre consists of a series of pieces in the form of discs, as first pointed out by Mr. Bowman, not immediately adherent to each other, however, but, as I find, held together by an intervening substance, so yielding and elastic as to admit of very close approximation of the discs to each other or their separation to a certain extent.

Diagram of the Structure of a so-called primitive Fasciculus of Muscle.

A, the discs closely approximated.

B, the discs separated.

a, discs. b, intervening substance.

These discs I consider analogous in their nature to *electro-magnets*; and I propose to call them *neuro-magnets*, inasmuch as the relation of the nervous influence to them appears to be essentially the same as that of the galvanic influence to the soft iron forming common electro-magnets.

The neuro-magnetic discs then composing muscular fibre are of microscopical minuteness, and are arranged so as to operate on each other at very

short distances only, and therefore with great power—a power which, as in other cases of attraction, goes on to augment, in a rapidly increasing ratio as the discs approach each other.

By the multiplication of the neuro-magnets in the linear series constituting a muscular fibre, due, though limited, extent of motion is obtained; and according to the number of linear series arranged side by side in a muscle so is the power of that muscle.

The primitive fibrils of the nerves are disposed in loops across the muscular fibres, but not coiled round the neuro-magnets as the galvanism-conducting wire is around electro-magnets when much electro magnetic force is required. But this is not a difference in principle, merely one in degree of arrangement; and, if my views are well founded, but another example of nature's simplicity and economy in means, but excellence and completeness in results.

The nervous influence streaming along the primitive fibrils of the nerves, thus disposed in loops across the muscular fibres, communicates to the neuro-magnetic discs composing these fibres, a magnetic state in the same way that the galvanism conducted by the wires of electro-magnets does to the soft iron, of which these magnets are composed.

By virtue of the magnetic state which the neuro-magnetic discs of muscular fibre thus acquire—some directly, some by induction—they attract each other: and this constitutes contraction of the muscular fibre. (Fig. A.)

The stream of nervous influence being arrested, the magnetic state of the neuro-magnetic discs of the muscular fibres is for the time suspended, and so relaxation of the muscles takes place by the discs being allowed to separate from each other as far as their intervening substance will permit. (Fig. B.)

According to the view I have now propounded of muscular contraction, the force with which it takes place must be greater towards the end than at the beginning of the action. This is quite contrary to the conclusion arrived at by Schwann from his carefully conducted experiments on muscular motion. But I believe Schwann erred in applying to *muscular fibre* what he ascertained in regard to certain *entire muscles* in which the component

* Extract from Mr. Wharton Jones's lecture introductory to his Course on Anatomy and Physiology, at the Charing Cross Hospital, delivered on Tuesday, the 3d October, 1843.

fibres are variously grouped and arranged—grouped and arranged in conformity with the duties the muscle has to perform. For the muscle having to overcome a greater resistance when it begins to act than afterwards, a greater number of fibres are so disposed as to come into play at the commencement—a smaller number at the end of its action.

The passive organs of locomotion constitute a system of levers, cords, and pulleys; the muscles being the agents for drawing the cords by which the whole is set into play.

The bones are by the joints fitted to move on each other in the manner of levers, of all the three kinds of which we find examples in the body.

* * * * *

A peculiarity in the levers of the body which I have now demonstrated to you, is the shortness of the arm of power in comparison with the arm of resistance; whereas in common mechanics it is always an object to have the arm of power as long as possible in comparison with the arm of resistance, for by this means less expenditure of force is required to overcome the resistance. This every one knows, and is well illustrated by the vaunt of the ancient philosopher, that he could by his own individual bodily strength move the world—provided he had a lever with a sufficiently long arm of power!

The question thus naturally arises, how is it that in animal bodies in which every object is effected at the smallest possible expense, whether of materials or power, there should be found such disadvantageous leverage?

Satisfactory reasons I believe may be given for this apparent anomaly.

In the first place, extent and rapidity of motion is obtained, space economised, and symmetry preserved; which you will admit are some equivalent for a considerable expenditure of power. But putting out of view those equivalents, I would remark that a power such as muscular contraction would have been inapplicable to long leverage. In fact, had long leverage existed, a much more complicated mode of applying the power than that which is adopted would have been necessary in order to effect the same results, whereas the short leverage presented by the

bones to the muscles is in strict conformity with all the phenomena of muscular action.

The attraction of the neuro-magnetic discs of which I consider muscular fibre to be composed, being, as in common magnetism, exerted with an available amount of force only at short distances, the shortening of muscular fibres in action is necessarily of comparatively limited extent. With this limited extent of contraction in the muscles then, short leverage was the only means of obtaining extent of movement of the bones. But as the very circumstance which limits the extent of contraction in the muscles, gives them great and increasing power in contracting, this more than counterbalances any loss by disadvantageous leverage.

TEST FOR CORROSIVE SUBLIMATE

To the Editor of the Medical Gazette.

SIR,

You did me the favour to insert in your journal of the 9th of last June, a letter in which I proposed pure metallic silver, obtained by precipitation with copper, as a test for corrosive sublimate; the trial of this agent having occurred to me on the ground of its bringing into play a double affinity instead of a single one, as where protochloride of tin is employed.

It is true that both metallic copper and tin, which have a like double action, had been long ago used as reagents for this substance; but there appeared no reason why silver might not possess some advantages over them, and I hope to make it probable in the sequel that it does so.

I believe that I should have left my process to take its chance with the public, and should have instituted no further inquiries into its powers, but for some comments upon it published under the signature of Forensis, in your numbers of the 4th and 11th of August. While no want of courtesy was to be complained of in the tone of the remarks alluded to, it seemed to me nevertheless, that the writer, by pursuing the somewhat antiquated plan of condemning upon theory a method the value of which can only be ascer-

tained by experiment (and of which he does not appear in any one instance to have made a trial), had created an unfair prejudice against it, and I became anxious to show that I had not brought forward a test so worthless as he seems to consider it. I cared not if my bantling died a natural death, but could not consent that he should thus lay violent hands on it.

In the first place it may be observed that nitrate of silver being for other uses often wanted in the laboratory, pure silver, in the state required, is very readily obtainable; nor can its cost be considered an objection to its employment, when it is stated that 3 or at most 4 grains are sufficient for an experiment, and that nearly the whole of it may be easily recovered.

At the outset, Forensis demurs to my saying that I was encouraged by the blackened appearance of the mixture to believe that decomposition of the bichloride had taken place, when corrosive sublimate and silver had been triturated together in a dry state; and having quoted the chemical law, "that bodies do not act upon each other unless one at least be in solution or contain water of crystallization," he proceeds not only to establish the correctness of my inference, but furnishes also a second exception to his just enunciated principle in the case of corrosive sublimate and tin.

Dr. Christison is next cited, where he says "that the solid compounds formed by corrosive sublimate with animal principles are either soluble in hydrochloric acid, or part with all their mercury to it. But this is not the case with the compound formed with vegetable principles." (Surely this statement is too general, and requires to be much modified, now that several animal and vegetable principles, as albumen, fibrin, and casein, are believed to be identical.) "Dilute hydrochloric acid, boiled for two hours on the compound formed in tea dissolves little of it, and leaves much undissolved powder, which yields by destructive distillation a large quantity of mercury." "Hence," says Forensis, "it must be evident that Dr. Frampton's process could not suit such a complication." I shall not stop to inquire how it can be ascertained be-

forehand that metallic silver may not act on a compound which offers no resistance to the protochloride of tin, but will briefly detail the most striking of several experiments. One grain of corrosive sublimate was dissolved in five drachms of distilled water, and half a drachm, that is, one-tenth of this solution, was added to four ounces of a moderately strong infusion of tea, and another half drachm to other six ounces of the same infusion: the mixture was left undisturbed in the former case for 38 hours, in the latter for four days and a half, or nearly 110 hours. At the end of these respective times hydrochloric acid was added, the mixture boiled in each case, and in both dark and abundant precipitates were observed after this treatment: in each case 3 grains of silver were boiled for some minutes in the mixture, the fluid was poured off, the precipitate digested in liquor potassæ, and washed with liquor ammoniæ, and dried, and a distinct ring of mercurial globules was in each obtained by means of heat applied to the amalgam thus obtained, and introduced into a small glass tube.

In these instances tea alone was employed: in a third experiment, one-tenth of a grain of corrosive sublimate, after remaining during 70 hours in a mixture of 9 ounces of tea and $1\frac{1}{2}$ ounces of milk with sugar, was detected by a like process. In this case the fluid was boiled for nearly two hours on the silver, from a belief that the continuance of the heat was favourable to the success of the experiment, so that 9 ounces of fluid only were drawn off, and the bichloride was separated from a mixture of 42,000 times its own weight.

Dr. Christison appears satisfied with detecting $\frac{1}{10}$ th of a grain in 4 ounces of a similar mixture of tea milk and sugar, *i. e.* in one of 19,200 times its own weight, by means of the protochloride of tin.

Forensis goes on to indulge his theorising propensities after the following fashion. "When bodies are dissolved in a fluid, the body, or solvent, appears to be uniformly diffused throughout the solvent; consequently the liquid reagents seem to act under circumstances of great advantage, at least as relates to delicacy, extent, and minuteness of division, and experiment proves what reason naturally infers. Nothing,

in fact, can equal protochloride of tin in solution, and the acids above named (viz., the phosphorous and hypophosphorous)." This general assertion of the superiority of liquid over solid reagents appears bold, if not rash, at a time when M. Reinsch's test for arsenic with copper is before the public, of which I see, in your number of this day (Oct. 7), Dr. Christison says that it will detect a 250,000th part of arsenic in a fluid, while others claim for it a much greater sensibility. M. Devergie, in his *Médecine Légale*, 1836, limits the sensibility of protochloride of tin, and of Smithson's pile, to detecting one part of corrosive sublimate in 80,000; and Orfila, in his new edition of *Toxicologie Générale*, claims for copper a nearly equal power; giving the preference to this test above all others. To shew the delicacy of silver as compared with these, and more especially with the protochloride of tin, I must again appeal to experiment. Distinct mercurial globules were obtained in one case by the process I have described, when I had mixed one-tenth of a grain of corrosive sublimate with 25 ounces of water supplied by the New River Company. Here, as the boiling was continued for some time, there was a loss from evaporation, so that 23 ounces only of fluid were drained off; but at the lowest estimate there was a sensibility to one part in 115,000. A ring, too, was obtained, and mercurial globules were made apparent on scraping with a pin, after another experiment, in which 1-16th of a grain of corrosive sublimate was mixed with 27 ounces of the same water, in which case 23½ ounces were drawn off, thus proving a sensibility to one in 180,000 parts; and it is probable that this is not the extreme limit of its power.

In order to detect corrosive sublimate in the liver of a man or animal poisoned by it, in which cases it probably often exists only in the blood within the vessels of the part, or to separate it when it has combined with certain substances, as albumen or gluten, it may frequently be necessary to have recourse to the previous treatment with nitro-hydrochloric acid recommended by Forensis, or to some other, such as may be found described by Orfila; but this previous treatment, when necessary at all, is

needed alike for the application of all the tests, and must be similar for all, so that it forms no ground of objection to that of silver.

The advantages of this test over protochloride of tin appear to me to be these:—1st, It is, as I think I have shown, more delicate. 2dly, Its application is far more easy and less tedious. The weight of the silver causes it to sink so readily to the bottom, and to remain so quietly there, that the little fibres, and leaves, and seeds, which Dr. Christison desires to be picked out, may, for the most part, be floated off. It does not precipitate organic matters, and has only to be freed from those adhering to it: protochloride of tin precipitates organic matters, which, with the oxide of tin, have afterwards to be dissolved: this precipitation, too, is slow; one operator allowing twenty-four hours for its subsidence. (Dr. Christison filters, but this is open to objection.) The precipitate is to be washed repeatedly, and twelve hours are required for subsidence after each washing, whereas in the case of silver each subsidence is instantaneous, and the amalgam may be very easily and thoroughly dried.

As compared with copper, silver appears to have the advantage of greater delicacy, and to require less time for its application—forty-eight hours being the time allowed by Orfila for its action where the proportion of corrosive sublimate is very small: probably, also, there is less risk of failure from the presence of foreign matters with the sublimed mercury, if I may judge from one of Orfila's experiments, in which he obtained, as he states, some empyreumatic oil, carbonate of ammonia, and several mercurial globules.

There are some other random assertions made by Forensis, which it would not be worth while to notice, even if my space allowed me to do so. I will now, therefore, take my leave of him, with the expression of a friendly wish that he may hereafter attain to that more advanced stage of knowledge which has a becoming modesty as its invariable accompaniment.—I am, sir,

Your obedient servant,
ALGERNON FRAMPTON.

29, New Broad Street, Oct. 7, 1843.

REMARKS

ON

FLOODING FROM THE UTERUS.

To the Editor of the Medical Gazette.

SIR,

MAY I request the insertion of the following in the columns of the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,

JOHN ROBINSON, M.R.C.S. L.A.C.

Long Buckley, Northamptonshire.

If a woman flooding after the expulsion of the placenta be placed in the recumbent position, especially if her head and shoulders be lowest, can syncope take place till it is almost fatal? If, however, she be put in the semi-recumbent posture, will she not faint away early and safely, and will not the duration of it be manageable, and may not the hæmorrhage be checked or stopped by *this*? A woman who has flooded till she resembles a fish out of water, is liable to subsequent weakness, and to puerperal disease, or even to die at the time. May not this liability be induced by protracting the period of actual fainting through the position of the female? It need not be said, that the quantity of blood lost by a patient under ordinary venesection is *cæteris paribus* as is the posture. Syncope occurs here, and blood ceases to flow forth. Is there no analogy between this and flooding? But it is said, rest is of importance. Is a woman, entirely reclining, especially if she lie on her back, quiet whilst flooding; does she not throw her arms about, raise her head, turn it about, endeavour to turn herself, and look as if she wished to be raised up?

Again, the grand object of the recumbent position is to favour the supply of blood to the brain, and to check its flow to the uterus. Three things must not be forgotten here. First, the tortuous course of the uterine arteries. Secondly, the fact that flooding to a most alarming extent does take place while the recumbent position is maintained. And thirdly, that syncope from diminished nervous energy, consequent on diminished circulation through the brain, is safe in proportion to the limit of the hæmorrhage, and the powers of the patient.

Many practitioners have a flooding person well pillowed under the shoulders

till she faints, and then have her gently laid down.

Of course it would be useless, and even dangerous, to raise a woman who had flooded whilst in the recumbent position.

This is not the time to inquire how much discharge, or how great effect on the system, constitutes flooding. Neither is it necessary to enumerate the several auxiliaries in the treatment of flooding. The fact is admitted, and the inquiry is, what is the best position?

Where there is "placenta prævia," how should the person be placed?

During natural labour, does not the long axis of the child's head correspond with the long axis of its shoulders, and both to the longest axis of the pelvis of the mother? If so, must not the caput succedaneum be as the chin of the child is turned towards the right or left shoulder? Thinking the subject of position for a female, flooding, practical in itself, and perhaps of some importance in a medico-legal sense, I have troubled you with a few remarks upon it, hoping they will be noticed by the readers of the MEDICAL GAZETTE as questions, not as answers.

VIVISECTION.

To the Editor of the Medical Gazette.

SIR,

I AGREE with your correspondents Dr. Hull and Mr. Macilwain, that the practice of vivisection is absurd; often from want of careful reading and comparing opinions on the part of experimentalists. But I think that the censures of your correspondents are too unlimited, made in wilful forgetfulness of the benefits which medical science has derived from experiments on animals, and with a leaning to unprofessional prejudice.

I will venture to weigh authorities with Dr. Hull: a worse one on such a subject than Dr. Johnson could scarcely be selected. That writer was the slave of prejudice, and we know that when prejudiced he refused to hear the voice of reason; moreover, as far as we can judge from his history, he was likely to be utterly unacquainted with the merits of the question on which nevertheless he pronounces with his wonted assumption. *My authority* is the great author

of the Inductive Philosophy, who, in the words of the learned Morhof, "digito quasi ostendit vias quas agmine facto jam multi" (should Dr. Hull take the trouble to consult the Polyhistor tom. 2, c. 1, p. 124, the next sentence to that of which I quote a part may furnish a sling at experimentalists). In the new Atlantis, which is a description of a scientific and literary Utopia, occur the following sentences:—"We have also parks and enclosures of all sorts of beasts and birds, which we use not only for view or rareness, but likewise for dissections and tryals, that thereby we may take light what may be wrought on the body of man. We try also all poysons and other medicines upon them, as well of chirurgery as of physic."

The experiments of Marshall Hall, Charles Bell, Orfila, and others, furnish such convincing proofs of the value of well devised and well conducted experiments on animals, that in my insignificant opinion the unqualified condemnation of vivisection is ignorant, or ungrateful and disgusting cant.

Physiological and toxicological experiments with remedial and poisonous agents introduce a comparatively rare groundwork of calculation on which we may proceed in reasoning of the obscure and contradictory phenomena presented during the treatment of disease. Such experiments are those of Orfila on the absorption of poisons, and late investigations which tend to prove that the chemical analogies of bodies are closely imitated by analogy of action on the living system.

We have heard of him who could mourn over a dead jackass and neglect a starving mother. Let charity begin at home, although it should not stop there. I would recommend humanity-mongers to attend to some of the barbarities committed under the name of *law*—to look at a poor maniac of 85, tottering on the brink of the grave already, put to death for a dispensation of the Almighty. And if they must have brutes to sympathize with, let them reckon up the tortures inflicted by the custom of pounding animals.

I am, sir,

Your obedient servant,

R. MORTIMER GLOVER, M.D.

Newcastle on Tyne,
Oct. 10, 1813.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégér."—D'ALEMBERT.

A Practical and Theoretical Treatise on the Diagnosis, Pathology, and Treatment of Diseases of the Skin: arranged according to a Natural System of Classification, and preceded by an Outline of the Anatomy and Physiology of the Skin. By ERASMUS WILSON. London: Churchill. 8vo. pp. 407.

THE great improvements which have taken place in medical science during the last few years are nowhere so conspicuous as in the increased knowledge which we possess of the structural anatomy and pathological changes of the component tissues of the animal body. Mr. Wilson has very happily availed himself of our improved acquaintance with these subjects in the work before us, and has established a classification of the diseases of the skin which is more scientific and perfect than any that have heretofore been proposed. It may be inferred that a classification founded on anatomical structure must necessarily be simple, but besides this we have no hesitation in declaring it to be thoroughly practical in all its bearings, and calculated to clear away much of the obscurity which has hung around these diseases for so many years. Another advantage not commonly attained of the "natural classification," as Mr. Wilson terms it, is the retention of the nomenclature which has been so long in use, so that we have not, as is too frequently the case with new arrangements of disease, to begin our schooling again, or be submitted to the annoyance of hearing our sons speaking in a language which is unknown to ourselves. Of the principles of the new classification of diseases of the skin, the author observes:

"The basis of the natural system of classification rests upon anatomy and physiology, and herein lies its strength, its simplicity, its easy application, and its truth. The dermis and its dependencies, its glands and its follicles, are the undoubted seat of all the changes which characterise cutaneous pathology. These, then, constitute my four *primary divisions*, namely:

1. Diseases of the dermis.
2. Diseases of the sudoriparous glands.
3. Diseases of the sebaceous glands.
4. Diseases of the hair and hair-follicles."

The dermis being the tissue the most complex in its nature and organisation, naturally offers the greatest number of pathological changes. These Mr. Wilson names his *secondary divisions*; they are —

Inflammation of the dermis.

Hypertrophy of the papillæ of the dermis.

Disorders of the vascular tissue of the dermis.

Disorders of the sensibility of the dermis.

Disorders of the chromatogenous functions of the dermis.

The entire bearings of Mr. Wilson's classification will, however, be better exemplified by the following tabular arrangement, which we quote from his preface.

I. DISEASES OF THE DERMIS.

Inflammation	Congestive	Specific	{ Rubeola. Scarlatina. Variola. Varicella. Vaccinia.
		Non-specific	{ Erysipelas. Urticaria. Roseola. Erythema.
	Effusive.	Asthenic	{ Pemphigus. Rupia.
		Sthenic	{ Herpes. Eczema. Sudamina.
	Suppurative		{ Impetigo. Ecthyma.
	Depositive		{ Strophulus. Lichen. Prurigo.
	Squamous		{ Lepra. Psoriasis. Pityriasis.
	From Parasitic Animalcules		Scabies.
Hypertrophy of the Papillæ			{ Ichthyosis. Tylosis. Clavus. Verrucæ. Cornua.
Disorders of the Vascular Tissue			{ Vascular Nævi. Purpura.
Disordered Sensibility			{ Hyperesthesia. Pruritus.
Disordered Chromatogenous Functions	Augmentation of pigment		{ Nigrities. Pigmentary Nævi.
		Diminution of pigment	{ Albinismus. Vitiligo.
	Alteration of pigment . .		{ Ephelis. Lentigo. Chloasma. Melasma.
		Chemical Coloration . .	Oxyde of Silver Stain.

II. DISEASES OF THE SUDORIPAROUS GLANDS.

Augmentation of Secretion	Sudatoria.
Diminution of Secretion.-	
Alteration of Secretion	Abnormal Odour, Colour, &c.

III. DISEASES OF THE SEBACEOUS GLANDS.

Augmentation of Secretion	Stearthœa.				
Diminution of Secretion.					
Alteration of Secretion	Ichthyosis Sebacea.				
Retention of Secretion	<table> <tr> <td>Duct open</td><td> { Comedones. { Sebaceous Accumulations. { Small Sebaceous Tumors. { (<i>Molluscum Contagiosum</i>.) </td></tr> <tr> <td>Duct closed.</td><td> { Sebaceous Miliary Tubercles. { Calcareous Miliary Tubercles. { Serous Cysts. { Encysted Tumors. </td></tr> </table>	Duct open	{ Comedones. { Sebaceous Accumulations. { Small Sebaceous Tumors. { (<i>Molluscum Contagiosum</i> .)	Duct closed.	{ Sebaceous Miliary Tubercles. { Calcareous Miliary Tubercles. { Serous Cysts. { Encysted Tumors.
Duct open	{ Comedones. { Sebaceous Accumulations. { Small Sebaceous Tumors. { (<i>Molluscum Contagiosum</i> .)				
Duct closed.	{ Sebaceous Miliary Tubercles. { Calcareous Miliary Tubercles. { Serous Cysts. { Encysted Tumors.				
Inflammation of Glands and adjacent Textures	{ Acne. { Sycosis.				

IV. DISEASES OF THE HAIRS AND HAIR-FOLLICLES.

Augmented Formation	Plous Nævi.
Diminished Formation	{ Alopecia. { Calvities.
Alteration of Colour	Canities.
Disease of the Hair-Pulps	Plica Polonica.
Disease of the Follicles	{ Inflammatio Folliculorum. { Favus.
Abnormal Direction	{ Trichiasis. { Felting.

Proceeding to the composition of the work, we find the first chapter dedicated to the anatomy and physiology of the skin; a proper, and, indeed, considering the late improvements in microscopic anatomy, a necessary introduction. This subject is ably and skilfully discussed by our author, and contains several points of peculiar interest; of which we can only make room for the following.

"The contractile fibrous tissue of the dermis has been demonstrated hitherto only in certain parts of the human skin, as in the nipples and scrotum, but it undoubtedly exists in the corium of every part of the body. It consists of fibres of a reddish hue, somewhat larger than those of areolar tissue, and semitransparent. These fibres are collected into fasciculi, sometimes lying parallel with each other, and forming membranous layers, at other times interlacing in every direction, and composing a firm web. They are met with in every part of the corium, but are most

abundant in the coarse network of its under surface. This tissue is easily perceived in the corium of some animals, where it forms a web around the sebaceous glands and hair follicles. It probably has the same arrangement in the skin of man; in the former situation acting as a compressor of the sebaceous gland, and an important auxiliary to the current of its secretion; in the latter producing an erection of the hairs analogous to the bristling which takes place in animals. That appearance of the skin produced by cold or fear, (spasmus periphericus,) that we term *cutis anserina*, or goose-skin, is due to the presence of this contractile fibrous tissue."

The diseases coming under Mr. Wilson's definition—congestive inflammation of the dermis—are described in the second and third chapters, the former comprehending scarlatina, rubecula, variola, &c. and the latter erysipelas, urticaria, roseola, and erythema. The study of the different

groups of diseases, both there, and throughout the book, is much facilitated by a short introduction on the general pathology of the group, which precedes each chapter. In reference to scarlatina, rubcola, and variola, the author revives the old notion of the Arabian physicians, of the origin of these diseases in the same morbid contagion, and conceives the differences between them to depend on modification either of the physical or of the vital conditions of the system by which the contagion is received. The exanthematous or eruptive diseases are "characterized by fever of greater or less severity, which precedes and accompanies the exanthem; by an exanthem, or inflammatory congestion of the dermis, which makes its appearance in the form of red points, and pursues a specific course; and by their mode of termination—namely, in resolution and desquamation of the epidermis in the two first, and by exudation and incrustation in the variolous affections; while all are liable to terminate by delitescence.

"Taking this view of the exanthematous diseases, I conceive myself warranted in placing the variolous affections in a group with which all their analogies harmonize. They correspond accurately with the definition I have given above; the premonitory symptoms present a close resemblance with rubcola and scarlatina; the eruption is identical at its first appearance, and the general management required is the same. At a later period, when variola assumes the pustular form, it must be regarded, as far as pathology is concerned, in the light of an advanced stage of rubcola and scarlatina, or as a severe type of the latter diseases depending its violence on the skin, instead of retrograding on the mucous membranes."

Under the name of the variolous diseases Mr. Wilson includes variola, varicella, and vaccinia; varicella, in its various forms of pustule, vesicle, and pimple, he treats as a modification of small-pox; and vaccinia as the small-pox of cattle. Into the latter subject he enters somewhat largely, describing the phenomena of the disease in the cow and in man, and the plans that have been suggested from time to time for the extension of the protective powers of vaccine inoculation.

The squamous diseases form the sub-

ject of chapter 7; diseases which are characterised especially by "inflammation of the dermis, and by the production of abnormal epidermis in the form of thin laminae or scales." The diseases included under this definition are lepra, psoriasis, and pityriasis, and of the analogy subsisting between them, Mr. Wilson remarks:—

"All dermatologists since the time of Willan are agreed as to the close analogy between these diseases, and the only innovation which has been suggested with regard to them is that of combining lepra and psoriasis under a single genus. If any useful purpose were to be gained by this reunion, I would cheerfully record my vote in its favour, for the similarity of lepra and psoriasis in their essential nature is so complete as to render them almost identical. On the other hand, it may be fairly advanced, that the terms are so well understood that no error can arise out of their separate existence, that time has rendered them classic sounds which could not well be dispensed with, and, moreover, that certain differences of moment are admitted between them, such as extent of surface occupied, duration, and severity.

"The type of these affections is the development of a squama or scale. According to Willan, a squama or scale is 'a lamina of morbid cuticle, hard, thickened, whitish, and opaque. Scales, when they increase into irregular layers, are denominated crusts.' Willan was desirous of rendering the language of dermatology so precise, that no misunderstanding could possibly arise with regard to the exact signification of the terms employed, but his followers have by no means trodden in his footsteps, and even himself has shewn some inconsistency. With the intention of superior precision, he limited the term crust to the layers of morbid epidermis developed in the scaly diseases. But at the present day we use it, somewhat loosely, to signify such collections on the surface of the skin as, from their extent and thickness, convey the impression of a mass greater than the acception usually assigned to the word scab. For instance, the thick, greenish-yellow concretion which forms in impetigo faciei, and covers the face like a mask, and which is truly a scab, we commonly call a crust, and Willan would seem to sanction the employ-

ment of the term in such a sense, by retaining the ancient appellation of this disorder—*crusta lactea*.”

Mr. Wilson very properly separates from the squamous group the disease termed ichthyosis: the grounds of this separation he thus expresses:—

“In his order ‘*Squamæ*,’ in addition to the three before-mentioned diseases, Willan admits a fourth—namely, ichthyosis. In this arrangement he is decidedly in error; ichthyosis bears no analogy whatever with the leprous affections. There is no inflammation of the skin in ichthyosis, no production of scales of morbid epidermis, but simply an increase in the quantity of normal epidermis, dependent upon a state of hypertrophy of the papillary layer of the dermis. For this reason I have assigned to ichthyosis its more appropriate position among those affections which are induced by hypertrophy of the papillæ of the skin, and am corroborated in this view by the concurrence of Rayer and Dr. Thompson.”

Respecting scabies Mr. Wilson advances some new views: he is a strong advocate for the parasitic origin of this disease, and regards the detection of the acarus as necessary to establish the diagnosis in any suspected case, when obscurity exists. The seventeenth chapter is dedicated to the history of this little animal, and forms a very curious episode to the work. It appears to have been known to Aristotle, and the Greeks; to the Arabians; and also to the ancient Romans; but the most ample and best account of the creature met with among the older authors is that given by the English writer Moutet, in his celebrated posthumous work, the “*Theatrum Insectorum*,” published in 1634, by Sir Theodore Mayerne. This chapter is concluded by Mr. Wilson’s own researches into the acarus scabiei. The following chapter is also occupied by the history of a parasitic animalcule inhabiting the sebaceous follicles of the skin, the acarus folliculorum, of which some figures, drawn by Bagg, face the title-page of the work. The existence of this creature was indicated by Dr. Simon, of Berlin, in a paper published in Müller’s *Archiv* for June 1842. Mr. Wilson was the first to observe it in this country, and after quoting Dr. Simon’s paper, he has added the result of his own researches. The largest of

these animals examined by Mr. Wilson measured $\frac{1}{84}$ of an inch in length; they are found in almost every person, and are quite consistent with a perfect state of health of the skin of the individual. The number usually met with in healthy persons is two, often four or five, and in one instance Mr. Wilson found as many as eight. They are situated near the mouth of the follicle, and have the head directed inwards. They are true insects, having a head, thorax, and abdomen, are provided with four pairs of legs, and they feed on the sebaceous substance in which they lie embedded.

The chapter on the diseases of sebaceous glands is copious, and contains, besides a well-digested view of the pathology of these organs, several subjects of original research, among which we note especially that alteration of the sebaceous matter to which Mr. Wilson has given the name of ichthyosis sebacea, and the so-called tubercular disorder, *molluscum contagiosum*. In reference to the latter disease the author observes:—

“In a third group, the secretion is not confined to the excretory duct and hair-follicle, but distends also the primary ramifications of the former, so as to give rise to a small tumor, about equal in size, in its fully developed state, to a ripe currant. This resemblance is not confined solely to size, for the sebaceous substance, rising to the aperture of the follicle in the centre of the tumor, appears like the depression on the summit of the currant to which the corolla is attached, while the sebaceous ducts swell out in the circumference of the tumor, and give to it a slightly lobulated appearance. When a transverse section of this little tumor is made, it is found in reality to be divided into five or six segments, each of the segments containing a dilated branch of the excretory duct. The swelling of these segments, moreover, gives rise to a depression on the summit of the tumor, corresponding with the aperture of the duct, from which a portion of the concreted sebaceous substance can always be removed by means of a pointed instrument, and it also produces a constriction around the base of the tumor.”

Some recent microscopic observations on the nature and contents of these little tumors, by Dr. Henderson

and Dr. Paterson, have raised a question relative to their pathology. Dr. Paterson inclines to the belief that the cellules which they contain are peculiar organisms, capable of nucleolar propagation when transferred to an appropriate nidus in another individual, and consequently constituting a contagious disease. Mr. Wilson, who is strongly opposed to the idea of their contagious nature, thus describes the contents of these tumors.

"On examining my new stock of sebaceous matter, (August 1842,) fresh from the patient, I found it to consist of cells heaped together like a pile of eggs, and intermingled with a large quantity of epidermic scales in flakes. The mass consisted solely of these two substances, without any granular matter or oil-globules. The cells were variable in their form, some being more or less cuboid, others irregular from compression, some oblong, like the eggs of the ant, others, again, oval, but the most common form was ovoid, like that delineated in the figures of Dr. Henderson and Dr. Paterson. The cells presented equal diversity in size, varying in their long diameter from $\frac{9}{100}$ to $\frac{7}{100}$ of an English inch, and in their short diameter from $\frac{1}{1333}$ to $\frac{1}{1111}$; some of the cuboid cells measured $\frac{1}{1000}$; the general size of the oval form was $\frac{6}{100}$ long, and $\frac{1}{1000}$ broad; there were several oblong cells, measuring $\frac{1}{333}$ by $\frac{1}{1111}$; and the common dimensions of the ovoid cells were $\frac{1}{200}$ by $\frac{1}{1000}$. This size corresponds very closely with the cells of ordinary inspissated sebaceous substance, whether it be conereted or pulpy; and also with the dimensions of the epidermic scales lying scattered among the cells. The contents of the cells were also various; some were filled with granular substance, in the midst of which, at some one point, the nucleus was perceptible; others contained a homogeneous substance, separated into polygonal masses, mostly of a cuboid shape; while others, again, were more or less filled with minute oil-globules. It is difficult to say which kind of cells were most numerous. I saw nothing like the double vesicle described by Dr. Paterson, and I think it possible that the appearance which he has delineated may have been produced either in the manner I have already suggested, or by the superposition of a single cell by several

connected scales of epidermis; or again by the accidental position of the cell upon the epidermic scales in such a manner as to constitute a thin margin around it."

The fifteenth chapter contains some curious observations relative to the abnormal growth and coloration of hair. Mr. Wilson does not despair of reproducing the hair when it has fallen off; the proximate causes of baldness he states to be defective development of the hair-pulps, defective circulation in the hair-pulps, and defective nutrition of the hair-pulps, and the treatment which he proposes is the following:—

"The principal indication to be fulfilled in the treatment of baldness, is to stimulate the capillary circulation of the scalp, which is evidently below the natural standard. With this view I am in the habit of recommending the washing of the head every morning with soap, drying it by friction with a rough towel, brushing it with a hard hair brush until redness is produced, and then applying some stimulating application, rubbed briskly into the scalp for five minutes. The application which I commonly advise is either the following spirit,

R Eau de Cologne, ʒij.; Tincture of Cantharides, ʒij.; Oil of Rosemary, Oil of Lavender, of each, ℥x. M.

or a pomatum containing cantharides or croton-oil; the latter requires care in its employment. I have also used iodine, in obstinate cases, with much success."

The chapter on diseases of the hair likewise contains a brief notice of the pathology of plica polonica, and the history and treatment of ring-worm; the concluding chapters of the volume being devoted to the cutaneous eruptions dependent on syphilis; the preparation and therapeutic virtues of two medicines of recent introduction, antrakokali and fuligokali; and some interesting cases of sweating sickness that were observed in Paris during the past year.

In concluding our somewhat long notice of this work, we pronounce it to be the best manual of cutaneous pathology in our language; the definitions of the various diseases are precise; the view taken of them by the author tends to simplify their study and comprehension; the pathology of the diseases is well explained; and the treatment is

sound and judicious. The reader will find here none of the wild speculations and rage for specifics that distinguish the writings of the continental authors.

The Prescriber's Pharmacopœia: containing all the Medicines in the London Pharmacopœia, arranged in Classes according to their Action; with their Composition and Doses. By a PRACTISING PHYSICIAN. 2d Edition. London. 32mo. 1843.: pp. 161.

THE call for a second edition of this little work at so short an interval after the appearance of the first, is a sufficient proof that its merit has been appreciated, and that the favourable opinion we passed upon it at its first appearance was not undeserved. In the present edition numerous additions have been made, and several changes adopted in the arrangement of the work, which considerably increase its utility. The principal of these are—

1. The arrangement of the different classes of medicines, as well as the individual articles in each class, in alphabetical order.

2. The separation, under a distinct head, of external remedies from those intended for internal use.

3. The addition, in the appendix, of several very useful tables relating to the temperature of baths—the proportion of the more powerful ingredients in certain pharmaceutical compounds—the proportionate doses of medicines at different ages—a classified list of the principal mineral waters, and the saturating proportions of alkalies and acids in saline draughts.

4. The reduction of nearly all the weights and measures to the same denomination, namely, grains, scruples, drachms, and ounces—the measures of pint and gallon being now rendered in ounces.

In addition to the officinal formulæ, the author has given a few which, though not contained in the Pharmacopœia, are in constant use: and perhaps a slight extension of this list in future editions might further improve the work. There are certain things of which it is by no means easy to obtain a knowledge simply because everybody is supposed to know them. For example, a student hears continually of "yellow wash," but he has not the least idea what it is composed of, and

he is ashamed to ask because everybody but himself seems to know. He may turn over a dozen big books on pharmacy without being any the wiser, and when at last he does learn, in some incidental manner, that it is composed of corrosive sublimate and lime-water, he may still remain ignorant of the proportions. If he refer to the "Prescriber's Pharmacopœia," he will find the following:—

5. [*Lotio Flava.* (Aqua Phagedenica). *Comp.* Hydrarg. bichlor. gr. ij.; aquæ Calcis, ʒj.]—which gives him, at a glance, the information he requires.

It is altogether a very useful little volume.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

UNHEALTHINESS OF LIVERPOOL.

DR. JOHNSON observed that the art of counting was in its infancy; and it must be confessed that it is still far from having attained a vigorous manhood. Conjecture takes the place of calculation; to serve the purpose of a political harangue, millions are added to the catholic population of one country, or the protestant population of another; and many a man is regaled with five thousand a year of London talk-money, who would be too happy did his income amount to half that sum in lawful British currency. The popular belief that London is as healthy as the country, a belief to be disproved by two lines of figures, is a familiar example of the neglect of the *méthode numérique*. Dr. W. H. Duncan, who has lately written a pamphlet on the high rate of mortality in Liverpool, gives another instance in point. After giving the opinion of several writers that Liverpool is remarkably healthy, he shows that, judging from the annual proportion of deaths to the population,

Liverpool is the most unhealthy town in England. Thus (omitting decimals), the annual deaths in London are 1 in 37 of the population; in Birmingham, 1 in 36; in Sheffield and Bristol, 1 in 32; in the Manchester Union, 1 in 29; but in Liverpool, 1 in 28. Again, while in London, of every 1000 deaths, 111 are at the age of 70 and upwards, in Liverpool there are only 54; and while 408 deaths out of every 1000 in London are below the age of 5, 528 occur out of the same number at Liverpool. This seems strange at first; but when the details of Liverpool life are explained, the mystery clears up: when we know the laws of nature,

“Comets are regular, and Wharfedale plain.”

A very large portion of the inhabitants of Liverpool live in courts and cellars; and, though it is true that the same evil in kind exists in all our towns, yet it would seem that, in its extent, Liverpool goes beyond all other English cities. The courts “consist usually of two rows of houses placed opposite to each other, with an intervening space of from 9 to 15 feet, and having two to six or eight houses in each row. The court communicates with the street by a passage or archway about 3 feet wide,—in the older courts built up overhead; and the farther end being also, in many instances, closed by a high wall, or by the back or side of an adjoining building; the court forms, in fact, a *cul de sac* with a narrow opening.”

It appeared, from an actual enumeration made two years ago, under the authority of the Town Council, that in the parish of Liverpool there were 1982 courts, containing 10,692 houses, and 55,534 inhabitants, being rather more than a fourth of the whole population!

As to the cellars, they “are 10 or 12 feet square; generally flagged, but frequently having only the bare earth

for a floor, and sometimes less than six feet in height. There is frequently no window, so that light and air can gain access to the cellar only by the door, the top of which is often not higher than the level of the street. In such cellars, ventilation is out of the question. They are, of course, dark; and, from the defective drainage, they are also very generally damp.”

Now, besides the inhabited cellars in the courts already mentioned, Liverpool contains 6,294 others, with 20,168 inhabitants.

Thus we have upwards of seventy-five thousand persons of the working classes living in wretched courts and cellars, besides crowds who are pent up in by-streets, ten, eight, or even five yards wide.

It will be naturally conjectured that the privies and ash-pits, the drainage and sewerage, are in costume with the noisome narrowness of these life-destroying abodes. And so they are. The cellar population have no place whatever to deposit their refuse matter, and the houses in the poorer streets are often in the same plight.

Thus, the Watch and Scavengers' Committee, in 26 streets of this calibre, among 1200 houses, found 804 without yard, privy, or ash-pits. The courts, too, though commonly possessing some conveniences of the kind, are in a filthy condition from their inadequacy. The ash-pits become full to overflowing, long before the nightmen empty them; and what ought to have found its way into these receptacles is deposited in the corners of the court, or in the adjoining street.

The fluid contents of these overcharged ash-pits sometimes ooze into the neighbouring cellars, where wells are dug to receive them, to prevent the inhabitants from being inundated. A well of this kind, four feet deep, and

gorged with the fetid fluid, was found in a cellar under the bed where the family slept. In another instance a cowkeeper used a cellar of this sort, filled with the poisonous liquid, to keep his milk in.

The drains and sewers are of a piece with these pestilential defects, and are, in part, their cause; for if these courts communicated with drains, the overflowings of the privies or ash-pits would find a proper vent. Within the last twelve years, indeed, more than £100,000 have been expended, under a local Act of Parliament, in the formation of sewers; but these have been built principally in the main streets, so that few members of the working classes have yet participated in the benefit of the Act.

The next element of mortality at Liverpool is the excessive crowding of the population. Take the most crowded district of London itself, and still you will find that Liverpool has attained the bad eminence of a yet more fatal accumulation of human beings. Mr. Farr thought that the maximum of crowding was attained in the East and West London Unions, where there are nearly 243,000 inhabitants to a square mile; but there is a district in Liverpool with nearly 12,000 inhabitants on a surface of 105,000 square yards, or at the rate of 460,000 inhabitants to the square mile.

It is obvious, however, that Mr. Farr may be in the right, as far as a *large* district goes; and it is very possible that in the Unions which he mentions there are portions as thronged as this populous region in Liverpool.

The straw-bespread lodging-cellars of Liverpool, which offer their penny accommodation to any and every one, may vie with the black hole of Calcutta. Thirty human beings are sometimes packed at night into a cellar containing 2,100 cubic feet, which will

correspond with a room twenty feet by fifteen, and seven feet high. Each of the thirty sufferers will thus have only 70 cubic feet, or less than one-fourth of the space necessary for free respiration. Indeed, according to Dr. Duncan, the Inspectors of Prisons in England recommend not less than 1000 cubic feet for each prisoner; and if this be meant of sleeping cells, as we suppose it is, each voluntary prisoner in the subterranean vaults of Liverpool has less than a fourteenth part of the room and air considered necessary in her Majesty's jails.

In consequence of these wretched habits, fever is far more prevalent in Liverpool than in the other great towns of England; so that while the deaths from fever in Birmingham and London are less than 5 per cent. of the total deaths, in Liverpool they are more than 6 $\frac{1}{4}$.

In the over-peopled district mentioned above, fever has its favourite abode; five hundred cases having been annually attended by the dispensary officers out of a population of less than 11,000. In Lace Street—the worst of the set—one inhabitant out of ten was yearly attacked by fever, on the average of five years.

The districts of Liverpool where fever is most prevalent are those where the Irish most abound.

Deaths from consumption, also, are most frequent at Liverpool; and deaths from convulsions and teething bear more than twice the ratio to the population in Liverpool that they do in London.

To other causes of mortality in Liverpool may be added the inefficiency of the scavenging and cleansing in the poorer streets; Dr. Duncan comparing the visits of the scavengers in these neighbourhoods to “angels’ visits,” *i. e.*, “few and far between.” The courts are not visited by them at all.

The crowded state of the dame and common day schools must likewise contribute its share to the mortality of children. Eight years ago, Mr. Riddall Wood found a school in a garret up three pair of dark, broken stairs, with forty children in the compass of ten feet by nine; and where "on a perch forming a triangle with the corner of the room sat a cock and two hens; under a stump-bed immediately beneath was a dog-kennel, in the occupation of three black terriers, whose barking, added to the noise of the children, and the cackling of the fowls on the approach of a stranger, was almost deafening. There was only one small window, at which sat the master, obstructing three-fourths of the light it was capable of admitting."

Dr. Duncan rejects various explanations which have been offered of the excessive mortality of Liverpool; as, for instance, that the Irish come from the country sick, and die there on their way home. For, though he allows that much of the excess in mortality is due to the resident Irish, he is confident that the Irish who leave Liverpool in bad health are far more numerous than those who arrive in that state. Yet this is not a conclusive proof; for these wanderers might take away more sick than they brought, and yet leave a host of dead behind. Nor, according to Dr. Duncan, can the high rate of infantile mortality be attributed to the refusal of the Irish to vaccinate their children, the relative proportion of deaths from small-pox being smaller in Liverpool than in Manchester.

Better times, however, are coming.

An Act for the promotion of the health of the inhabitants of Liverpool was passed last year, and came into operation on the 1st of November, 1842. We may possibly discuss its provisions on some future occasion. At present, we will only observe that

a hygienic code is imperatively wanted for all our great towns. The indigent are not strong enough to resist builders and landlords; nor have they even the firmness to do what is in their own power for health and safety:

*Crede mihi, miseros prudentia saepe reliquit,
Et sensus cum re, consiliumque facit.*

PHYSICIAN PRACTISING AS AN APOTHECARY.

WITHOUT considering the question, whether it would be better or not for physicians to get their livelihood by the sale of drugs, it cannot be denied for a moment that if a person accept honours under certain conditions, and, having obtained them, he break through those conditions, he does not do that which society in general consider *right*; and he (if he have any feeling,) can never be free from the consciousness that he is acting wrong. We shall see what the College will do in this case.

London, Oct. 10, 1843.

[ADVERTISEMENT.]

To the Editor of the "County Press."

SIR,

I wish to state, through the medium of your journal, that my having obtained the degree of Doctor of Medicine will *not* cause me to discontinue *any* branch of my profession, or to make the slightest alteration *in the terms* of attendance from those heretofore adopted by my predecessors, the Messrs. Colbeck, and subsequently by myself.

I am, Sir, Yours, &c.

FRED. GEO. REED,

Member of the Royal Colleges of Physicians and Surgeons, London.

Fore Street, Hertford, Oct. 6, 1843.

[We trust there is some mistake about this, and if so, we shall be happy to correct it.—ED. GAZ.]

COLLEGE OF SURGEONS — NEW CHARTER.

A NEW CHARTER has been granted to the College of Surgeons, a copy of which we subjoin:—

Charter.

Victoria, by the Grace of God, of the United Kingdom of Great Britain and Ireland, Queen, Defender of the Faith, to all

to whom these presents shall come greeting, Whereas the Body Politic and Corporate of The Royal College of Surgeons in London was incorporated or re-established under or by virtue of a certain Charter or Letters Patent, bearing date at Westminster, the twenty-second day of March, in the Fortieth Year of the Reign of King George the Third, or otherwise, as in such Letters Patent mentioned or referred to, and the said College is now regulated and governed by and according to the Provisions of such Charter or Letters Patent, and a certain other or Supplemental Charter, granted by Letters Patent, bearing date at Westminster, the thirteenth day of February, in the Third Year of the Reign of King George the Fourth, and also by or according to certain Bye-Law and Ordinances made by the said College for its regulation and better government.

And whereas the Body Politic and Corporate of the said College at present consists of Persons created Members of the said College by the said first-mentioned Charter, or constituted such Members by Letters Testimonial, under the Common Seal of the said College, of the respective qualifications of such persons to practise the art and science of Surgery. And the Governing body of the said College consists of a Council of twenty-one of the Members of the College, ten of them being also Examiners of Surgeons for the College, and one of such ten persons being also the President and two of them the Vice-Presidents of the College and the two principal Serjeant-Surgeons to us and to our Heirs and Successors and the Surgeon-General to the Forces, of us, our Heirs and Successors, provided they shall have been chosen Members of the Council, have at present a preference of being admitted Examiners of the said College before all other persons whenever vacancies happen in the Court of Examiners of the College.

And whereas, in order more effectually to promote and encourage the study and practice of the said art and Science of Surgery, It appears to us expedient, that a new class of Members of the said College, to be called Fellows, should be created, and (with the exception of the first Fellows hereinafter named and directed and authorized respectively to be appointed) be required, in order to obtain the Diploma of their Fellowship, to have attained a greater age than is at present necessary in the case of ordinary Members of the said College, and to have complied with such Rules and Regulations, and passed such Examination as hereinafter mentioned; That the number of the Members of the Council of the said College should be increased, and that all future Members of the Council be chosen from the Fellows of

the College and hold their office for a limited period only, instead of for life, and that the right of electing Members of the Council be transferred from the Council (with whom such right now resides) to the Body of such Fellows; That alterations be also made as regards the election and admission and continuance in office of the future Examiners of the College, and that certain further powers and privileges should also be granted to the said College. Now know ye, That We, of our especial grace and mere motion, at the Humble Petition of the said Royal College have willed, ordained, constituted, and declared and granted, and by these presents for us, our Heirs and Successors, do will, ordain, constitute and declare, and unto the said Royal College of Surgeons in London do grant, in manner following, to wit:

1. That from henceforth the Corporate Name or Style of the said College shall be—The Royal College of Surgeons of England, and that a portion of the Members of the said College shall be Fellows thereof by the name or style of The Fellows of the Royal College of Surgeons of England.

2. That the present President and two Vice-Presidents, and all other the present Members of the Council of the said College, and also such several other persons, not being less than two hundred and fifty nor more than three hundred in number, and being Members of the said College, as the Council of the said College, at any time or times before the expiration of three calendar months from the date hereof, shall elect and declare to be Fellows in manner hereinafter directed, together with any such other persons as the Council of the said College, after the expiration of the said three calendar months, and within one year from the date hereof, shall think fit and shall appoint in manner hereinafter authorized, shall be fellows of the said College.

3. That the Council of the said College, with all convenient speed after the date of these our Letters Patent, and before the expiration of three calendar months from the date hereof, and in such manner as the said Council shall deem best, shall elect to be Fellows of the said College, any such number of persons, being Members of the said College, and not being in the whole less than two hundred and fifty nor more than three hundred, as the said Council shall think proper: And also shall, before the expiration of such three calendar months, by one general Diploma, under the Seal of the said College, and in such form as the Council shall think fit, declare, or cause such persons to be declared Fellows of the Royal College of Surgeons of England accordingly; but the names of all such persons, so declared Fellows, shall be contained and set forth in a Schedule to such

general Diploma. And such general Diploma shall also, within two calendar months after the Seal of the said College shall have been affixed thereto, be enrolled in our High Court of Chancery.

4. That it shall also be lawful for the Council of the said College, at any time or times after the expiration of the said three calendar months and before the expiration of one year from the date hereof, by Diploma or Diplomas under the Seal of the said College, and in such form as the said Council shall think fit, and without any Fee, to appoint any other person or persons (being a Member or Members of the said College) to be a Fellow or Fellows of the said Royal College of Surgeons of England.

5. That, except as hereinbefore mentioned, no person shall become or be admitted a Fellow of the said College until after he shall have attained the age of twenty-five years, and shall also have complied with such Rules and Regulations as the council of the said College shall from time to time consider expedient, and by a Bye-Law or Bye-Laws direct, nor unless he shall have passed such special Examination by the Examiners of the said College, as the Council shall from time to time think fit, and by a Bye-Law or Bye-Laws direct, that Candidates for a Fellowship of the said College shall undergo; but every fit and proper person having attained such age, and complied with such Rules and Regulations, and passed such special Examination, shall be entitled to be admitted a Fellow of the said College.

6. That the admittance of every such new Fellow as last mentioned, shall be by Diploma under the seal of the said College, in such form as the Council of the College shall from time to time think fit and direct; and that every person so admitted a Fellow of the said College, and not being already a Member thereof, shall also, by virtue of such his admittance as a Fellow, become and be considered admitted as a Member of the said College.

7. That the Fee to be paid on the admittance of every such new Fellow as last aforesaid (over and besides the stamp-duty on his admittance or Diploma), shall be any such sum not exceeding the sum of Thirty-one Pounds Ten Shillings, as the Council of the said College shall from time to time think fit, and by a Bye-Law or Bye-Laws direct.

8. That where several Diplomas shall be granted on the same day (whether to such new Fellows as last aforesaid, or to any Fellows to be created after the said first three calendar months, and within the first year from the date hereof as aforesaid), such Diplomas shall be numbered under such Regulations as the Council may think fit, in order to show the order and priority of such Diplomas among themselves.

9. That the Council of the said College shall cause the name of every Fellow for the time being of the said College, and if thought fit by the Council, together also with the place of residence of every such Fellow, to be entered according to their several seniorities (in the manner and to be determined or ascertained respectively as hereinafter mentioned), in a Book or Register to be kept for that purpose at the Hall of the said College, or such other place for the time being as the said Council shall direct; and such Book or Register of Fellows, at such times, and subject to such reasonable and proper Regulations as the Council for the time being shall think fit and direct, shall be open to the inspection of any Member of the said College (whether Fellow or not), at the Hall of the said College, or other place appointed for the time being for the custody of the same. And the Seniority of such Fellows to be entered in such Book or Register as aforesaid, shall be and be determined or ascertained respectively as follows, that is to say, The present President shall be entered first, the two present Vice-Presidents, according to their respective seniority next after him, and then all the other present Members of the Council according to their respective seniorities; and immediately after such the present Members of the Council; the Fellows to be elected within three calendar months from the date hereof as hereinbefore directed, according to the order and priority of their names, as the same shall be contained and set forth in the Schedule to such general Diploma, whereby they shall be so declared Fellows as hereinbefore directed; and, with respect to all other Fellows, their names shall be entered according to the dates of their respective Diplomas; and when the Diplomas of any Fellows shall bear date on the same day, then as regards or between such Fellows according to the order and priority in which the diplomas shall be so numbered, as hereinbefore directed.

10. That from henceforth no Member of the said College, who shall not also be a Fellow of the same, shall be eligible as a Member of the Council of the said College; nor (but subject and without prejudice to the validity of any Election to be made as hereinafter directed) shall any Fellow be so eligible whilst practising Midwifery or Pharmacy, or who shall have practised Midwifery or Pharmacy at any time during the five years next preceding the day of Election, nor unless he shall reside and *bona fide* practise his profession of Surgeon within five miles by highway or road from the General Post-Office in St. Martin's-le-Grand. And if any Member of the Council shall at any time after his election practise Midwifery or Pharmacy, or shall cease to reside and *bona fide* practise his profession of Surgeon within five miles of the General Post-Office,

as aforesaid, he shall be liable to removal from the Council.

11. That the present Members of the Council of the said College shall be and continue Life Members thereof as heretofore, and that the number of the Members of the Council shall in the manner hereinafter mentioned be increased from twenty-one to twenty-four, and that all future Members of the Council shall be elective, and be elected periodically, in the manner and subject to the regulations hereinafter mentioned and directed.

12. That upon the first Thursday in the Month of July in the year one thousand eight hundred and forty-four, or within one calendar month afterwards, and in the manner hereinafter mentioned, three Fellows of the said College shall be chosen to be additional Members of the Council of the said College; and that upon the first Thursday in July in every succeeding year, for ever thereafter, or within one calendar month afterwards, and in the manner hereinafter mentioned, three Fellows shall be chosen to be Members of the Council; and in every such succeeding year in which there shall be no vacancy, or less than three vacancies among the Life Members of the Council, three of the Elective Members of the Council, or such less number of such Elective Members as, with the number of vacancies in that year among the Life Members, will make up the number, three shall go out of office upon the day whereon such three Fellows shall be chosen to be Members as aforesaid, so that the number of the Council shall at no time exceed twenty-four; and in every such succeeding year in which there shall be three or more than three vacancies among the Life Members, none of the Elective Members shall go out of office in that year, and three Fellows, and three only, shall be chosen to fill up three of such vacancies among the Life Members, and the remaining vacancy or vacancies of that year (if any) shall be considered and treated as a vacancy or vacancies among the Life Members in the following year or years, as the case may be or require. But from and after the period when the number of the Elective Members of the Council shall be completed and made up to twenty-four, three of the Members of the Council shall go out of office every year, upon the day whereon three new Members shall be elected, as aforesaid. But in all cases Fellows going out of office shall notwithstanding be eligible for nomination and immediate re-election, and continuing eligible in other respects, their names shall be announced to the Meeting accordingly in the order and manner hereinafter directed.

13. That the Elective Members of the Council, who shall from time to time go out of office in the manner hereinbefore men-

tioned and directed, shall be those who shall have been longest on the Council without re-election; and in the case of Fellows elected upon the Council in the same year, those shall first go out of office whose names stand lowest (among those elected of the same year) on the Book or Register of the Fellows of the College.

14. That whenever any vacancy or vacancies shall take place among the Elective Members in any other way than by their going out of office by rotation as aforesaid, such vacancy or vacancies shall be filled up by the election (upon some early and convenient day to be fixed by the Council for that purpose) of a substitute Member or Members in the room of the person or persons whose place or places shall have so become vacant; and every person, so elected to fill up any such vacancy, shall hold such office until the time when the person in whose room he shall be chosen would have been liable to go out of office, and he shall then go out of office accordingly, but shall notwithstanding be eligible for nomination and immediate re-election, and, continuing eligible in other respects, his name shall be announced to the Meeting accordingly in the order and manner hereinafter directed.

15. That the Members of the Council of the College shall hereafter be elected by the Fellows of the said College, including the Members of the Council as such; and such Fellows, whether Members of the Council or not, shall be allowed to vote in person only and not by proxy; and that any number of Fellows (not being less than fifteen present) at a Meeting convened for the purpose of electing a Member or Members of Council, shall be competent to proceed as such Election.

16. That the Chair at every such Meeting shall be taken by the President of the said College, or in his absence by one of the Vice-Presidents, or in case also of their absence, then by the senior Member of the Council of the said College then present. And if it shall so happen that from any cause the business of the day cannot be concluded upon such the day fixed for election as aforesaid, then and in every such case an adjournment of the Meeting shall take place to the next day, at an hour to be named by the Chairman (Sundays, Christmas-days, and Good Fridays excepted, and being passed over when occasion shall require), and so from day to day (except as aforesaid) until the business of the Meeting shall be completed; but no other business shall be discussed or attended to at any such meeting besides the election of a Member or Members of the Council, for which the same shall have been convened. Provided also, that if upon the day fixed for any such Election there shall not be fifteen or more Fellows assembled and continuing together for the pur-

pose of such Election, then at any time after the space of one hour after the time of day fixed for such Election the Chair may be taken as aforesaid, and it shall be lawful for the Chairman to adjourn the Meeting to the next day, and so from day to day (except as aforesaid) if necessary, in the manner hereinbefore mentioned with respect to adjournments of such Meetings in case of the business thereof not being concluded as aforesaid.

17. That such previous notice or notices of every election of a Member or Members of the Council shall be given as the Council shall from time to time think fit, and shall by a Bye-Law or Bye-Laws determine and appoint, and that, subject only to the regulations and restrictions in these our Letters Patent mentioned or contained, the election of Members of the Council shall be conducted in such way and manner as the Council shall from time to time think fit, and shall by a Bye-Law or Bye-Laws also determine or regulate and appoint, but such Election shall always be by Ballot, and be decided by a majority of balls or votes, and every Fellow who shall be eligible to be elected according to the regulations and restrictions contained or mentioned and authorized in or by these our Letters Patent, shall be announced to the Meeting as a Fellow eligible in the order and according to the priority in which his name shall stand in the book or registry of Fellows; and if he shall be thereupon nominated in such mode as the Council shall by Bye-Law or Bye-Laws provide for the general nomination of Members at Elections, he shall be balloted for accordingly, but not otherwise.

18. That when any eligible Fellow shall have been passed by for want of any such nomination as aforesaid, or having been balloted for shall not be elected a Member of the Council, he shall cease to be eligible to be elected, except upon such special terms of nomination as shall by the Council by Bye-Law be for the time being provided for such cases, and upon such special terms any Fellow so passed by or not elected, may be re-nominated for and be elected a Member of the Council, but if he shall be on such second occasion either passed by or not elected, he shall for ever thereafter cease to be eligible for election upon the Council.

19. That no Fellow whatever shall be eligible to be a Member of the Council unless at the time of his nomination for election as such there shall also be produced and delivered in, in such way and manner and in such form as the Council shall from time to time think fit and by Bye-Law regulate and appoint accordingly, a Certificate in writing signed by such number of Fellows as by such Bye-Law shall be required, that, or to the effect that such Fellow so nominated is a fit and proper person to be a Member of the Council, and particularly that he does not

practise, and has not within five years practised Midwifery or Pharmacy, and that he resides and *bonâ fide* practises his profession of a Surgeon within five miles by highway or road from the General Post Office in Saint Martin's-le-Grand, and such nomination and certificate being delivered in the manner required, the same (as regards the matters or particulars so to be certified as aforesaid, but no further) shall be final and conclusive as to the right of such Fellow to be balloted for as a Member of the Council, and also to be elected such Member if upon the Ballot he shall be so elected.

20. That there shall be Ten Examiners of Surgeons for the said College, and the present Examiners shall be and continue such Examiners for life as heretofore. But that the two principal Serjeant-Surgeons to Us and to our Heirs and Successors, and the Surgeon-General to the Forces of Us, our Heirs and Successors, or any of them, and although they may be chosen Members of the Council of the said College, shall no longer have any preference of being admitted Examiners of the said College before other persons; and that all future Examiners of the said College shall be elected by the Council of the College, either from the Members of the Council or from the other Fellows of the said College, or from both or either of them; and that all future Examiners of the said College shall hold their office of Examiners during the pleasure of the Council, and so long only as the Council of the College shall think fit.

21. That the President and Vice-Presidents of the said College shall no longer be chosen exclusively from or out of the Examiners of the said College, but from or out of all the Members of the Council indifferently, and whether Examiners of the College or not. And that any number of Examiners of the College, not being less than Six, shall be sufficient to form a Court of Examiners, and with or without the President or Vice-Presidents of the College, or any of them (and whether or not the President or Vice-Presidents, or any of them, may be Examiners).

22. That if it shall at any time hereafter appear that any present or future Member, or any Fellow of the said College, to be appointed or admitted at any time after the expiration of the said first three calendar months from the date hereof, shall have obtained his Letters Testimonial or his Diploma respectively by any fraud, false statement, or imposition, or that either before or after obtaining such his Letters Testimonial or Diploma, he shall have violated any Bye-law, Rule, or Regulation of the said College, then and in every such case, and after such previous notice to, and such hearing of, such Member or Fellow as, under the circumstances, the Council of the said

College shall think proper, it shall be lawful for such Council to recal and to declare the Letters Testimonial or Diploma respectively of such Member or Fellow to be void, and thereupon every such Member or Fellow shall cease to be a Member, or a Member and Fellow of the said College, as the case may be accordingly.

And We do further declare our Will and Pleasure to be, That except in the respects hereby altered, the said College and the Council of the same shall continue to have all such and the same jurisdiction, powers, authorities and discretions for and with respect to the government of the said College and the election and choice of the Officers of the same, as well as the admission and expulsion of Members and Fellows, and for the making, ordaining, confirming, annulling, or revoking Bye-Laws, Ordinances, Rules and Constitutions, and transacting and ordaining all other matters and things whatsoever for the regulation, government and advantage of the said College, as such College and the Council thereof respectively now have under or by virtue of the said two several herein-before recited or mentioned Charters or Letters Patent, or either of them respectively, or in any other lawful manner.

And we do hereby for Us, our Heirs and Successors, grant and confirm unto them all such jurisdictions, powers, authorities and discretions accordingly; Provided always, and it is our further Will and Pleasure, that no Bye-Law or Ordinance hereafter to be made by the said Council shall be of any force until our approval thereof shall have been signified to the said College under the hand of one of our Principal Secretaries of State, or the same shall have been otherwise approved in such manner as shall be directed by Us, with the advice and consent of the Lords Spiritual and Temporal and Commons of our Realm, in Parliament assembled.

And We do hereby for Us, our Heirs and Successors, further grant unto the said College, that these Our Letters Patent, or the Enrolment or Exemplification thereof, shall be in and by all things good, firm, valid, sufficient, and effectual in the Law, according to the true intent and meaning thereof, notwithstanding the not fully or not duly reciting the said several Letters Patent, or the dates thereof, or any other omission, imperfection, defect, matter, cause, or thing whatsoever, the same or any Rule or Law to the contrary thereof, in anywise notwithstanding. In witness whereof We have caused these Our Letters to be made Patent. Witness Ourselves at Our Palace at Westminster, this Fourteenth day of September in the Seventh Year of Our Reign.

AN
INTRODUCTORY DISCOURSE
ON THE
DUTIES AND CONDUCT OF MEDICAL STUDENTS AND PRACTITIONERS,

*Addressed to the Students of the Medical
School of St. George's Hospital,
October 2, 1843,*

By SIR BENJAMIN C. BRODIE, Bart.
F.R.S. &c. &c.

GENTLEMEN,—A large proportion of those whom I now address are assembled, for the first time, for the purpose of pursuing their studies in the Medical School of this Hospital; and their feelings on this occasion are not unknown to me; for, to a great extent at least, they must be such as I myself experienced, when long ago I was situated as they are at the present moment. Transplanted, perhaps, from some small community into this great city; the largest, the most populous, the richest that ever flourished; jostled in crowded streets; surrounded by palaces; where the high-born and the wealthy; where the most eminent statesmen; the most distinguished in literature, in sciences, and arts, and in every other human pursuit, are, as it were, fused into one mass to make the London world: contemplating the novel scene around you, but being not yet identified with it; it cannot be otherwise than that a sense of loneliness should come upon you in the intervals of excitement; that you should say, "What am I in the midst of so much bustle, activity, and splendour? who will be at the pains to watch the course of a medical student? who will know whether I am diligent or idle, or bear testimony in after-years to the correctness or irregularity of my conduct during this brief period of my life?"

830.—XXXIII.

But let not your inexperience lead you into so great an error. Even now, when you believe that no one heeds you, many eyes are upon you. Whether you are diligent in your studies; striving to the utmost to obtain a knowledge of your profession; honourable in your dealings with others; conducting yourselves as gentlemen; or whether you are idle and inattentive; offensive in your manners; coarse and careless in your general demeanour; wasting the precious hours, which should be devoted to study, in frivolous and discreditable pursuits; all these things are noted to your ultimate advantage or disadvantage; and in future days, you will find that it is not on accidental circumstances, but on the character which you have made as students, that your success as practitioners, and as men engaged in the business of the world, will mainly depend. By the time that you are sufficiently advanced for your lot in life to be finally determined, the course of events will have wrought mighty changes among us. Of those who are now the most conspicuous in station, and the most influential in society, many will have altogether vanished from the scene of their former labours; and others will be to be found only in the retirement of old age. Younger and more active spirits, your own cotemporaries, and those a little older than yourselves, will have occupied their places; and the tribunal, by which you will be judged of hereafter, will be composed of a different order of individuals from those to whose favourable opinion you would at this moment be most anxious to appeal.

But I should be sorry if I were misunderstood as representing this to be the only, or the principal motive, which should lead you to avail yourselves to the utmost of your present opportunities. The knowledge which you will obtain as students, is to be the foundation of the whole of that, which many years of professional practice will afford you afterwards; and, if the foundation be insecure, the superstructure will be of little

value. However imperfect may be the sciences belonging to the healing art, to bring them even to their present state has been the work of centuries. The industrious student may enter on the active pursuit of his profession with a scanty store of knowledge compared with that of which he will find himself possessed twenty years afterwards : but he is in the direct road to greater knowledge. He has the advantages of principles which have been established by the labours of many preceding generations ; and this will render the subsequent efforts of his life comparatively easy. But he who has neglected his education must, as it were, begin anew ; and he will find, when it is too late, that no combination of energy and talent will enable him to rise to the level of those who were, in the beginning, his more diligent competitors. He will, moreover, labour under another and still greater disadvantage. One business of education is to impart knowledge ; but another, and still more important one, is to train the intellectual faculties. To acquire the habit of fixing your attention on the object before you ; of observing for yourselves ; of thinking and reasoning accurately ; of distinguishing at once that which is important from that which is trivial ; all this must be accomplished in the early part of life, or it will not be accomplished at all : and the same remark is not less applicable to qualities of another order. Integrity and generosity of character ; the disposition to sympathise with others ; the power of commanding your own temper ; of resisting your selfish instincts ; and that self-respect, so important in every profession, but especially so in our own profession, which would prevent you from doing in secret what you would not do before all the world ; these things are rarely acquired, except by those who have been careful to scrutinise and regulate their own conduct in the very outset of their career.

It cannot be too often brought before you, nor too earnestly impressed upon your minds, that being, in the present stage of your journey through life, in a great degree released from responsibility to others, your responsibility to yourselves is much increased. Your future fortunes are placed in your own hands ; you may make them, or mar them, as you please. Those among you, who now labour hard in the acquirement of knowledge, will find that they have laid in a store which will be serviceable to them ever afterwards. They will have the satisfaction of knowing that, in practising their art for their own advantage, they are, at the same time, making themselves useful to their fellow-creatures : when they obtain credit, they will feel that it is not undeserved ; and a just self-confidence will support them even in their failures. But for

those who take an opposite course, there is prepared a long series of mortifications and disappointments. Younger men will be placed over their heads. Even where their judgment is correct, they will themselves suspect it to be wrong. With them, life will be a succession of tricks and expedients ; and if, by any accident, they should find themselves elevated into situations for which they have not been qualified by previous study, they will find that this is to them no good fortune ; the world will always compare them with better persons, and the constant anxiety to satisfy others, and to keep themselves from falling, will destroy the comfort of their existence. Whether it be in our profession or any other, I know of no individuals much more to be pitied than those whom fortuitous circumstances have lifted into places, the duties of which they are not well qualified to perform.

I trust that none among you will suspect that these observations are founded on any theoretical view of the subject, or that it is merely as a matter of course that I thus address myself to younger men. I wish to see those who are educated in this hospital, an institution to which I am indebted for so many advantages which I have possessed in life, go forth into the world useful and respectable members of an honourable and independent profession. I wish to see them obtain success, and worthy of the success which they obtain : and having now had a long experience in the history of medical students, and having been careful to watch their progress through life, I am satisfied that the only method by which this can be accomplished, is that which I have pointed out : and, I may add, that I have never known an individual, who thus applied himself seriously and in earnest to his task, whose exertions were not rewarded by a reasonable quantity of professional success—such as would be sufficient to satisfy any but an inordinate ambition. Beyond this, your lot in life may indeed be influenced by circumstances not altogether under your control. Accident may place one individual in a situation more favourable, and another in a situation less favourable to his advancement. One may have the advantage of greater physical powers, enabling him to undergo the same exertion with less fatigue, and to preserve his energies unimpaired, where those of another would be exhausted ; and, in like manner, one may have the advantage of powers of intellect which are denied to his competitors.

With respect, however, to the last-mentioned subject, I have no doubt that the difference is not so great as you, or the world generally, may suppose it to be. There are few persons who have not some talent, which, if properly cultivated, may be

turned to good account, and he who is deficient in one kind of talent may excel in another. But the greatest talents may be wasted. They may be blighted by indolence; they may be used for base or improper purposes; or, they may be directed to too great a variety of objects. It is well indeed for you to have some diversity of study, so as to keep all your mental faculties in wholesome exercise; so that you may not be without some sympathies with those around you, and that you may avoid the evils of narrowmindedness and prejudice; still, whoever would be really useful in the world, and be distinguished in it, must act to a great extent on the principle of concentration, keeping one object especially in view, and making his other pursuits subservient to it. And let no one sit down in despair and say, "I have not the abilities of my neighbours, and it is needless for me to exert myself in competition with them." If you would know what your own powers are, you must try to use them. Industry is necessary to their development; and the faculties of the mind, like those of the body, go on improving by cultivation. It is impossible for you to form a right estimate of yourselves in early life, nor can you be rightly estimated by others. The self-sufficient, who do not keep before their eyes an ideal standard of perfection, who compare themselves only with those who are below them, will have an advantage with inexperienced and superficial observers; but I must say that I have never known any one to do any real good in the world, or obtain ultimately a bright reputation for himself, who did not begin life with a certain portion of humility. The greatest men are humble. Humility leads to the highest distinction, for it leads to self-improvement. It is the only foundation of a just self-confidence. Study your own characters; endeavour to learn, and to supply your own deficiencies; never assume to yourselves qualities which you do not possess; combine all this with energy and activity, and you cannot predicate of yourselves, nor can others predicate of you, at what point you may arrive at last. "Men," says M. Guizot, "are formed morally as they are formed physically. They change every day. Their existence is always undergoing some modification. The Cromwell of 1650 was not the Cromwell of 1649. It is true that there is always a large stock of individuality: the same man still holds on; but how many ideas, how many sentiments, how many inclinations have changed in him! What a number of things he has lost and acquired! Thus, at whatever moment of his life we may look at a man, he is never such as we see him when his course is finished." These eloquent and philosophical remarks, made by the present Prime Minister

of France, are not more applicable to those who are engaged in politics, than they are to those who are engaged in the pursuits of private life, and to none more than to yourselves.

It is not my intention on this occasion to give you any advice as to the detail of your studies. It is best that this should be left to your respective teachers. They will tell what lectures you should attend first, what afterwards; what hours you should devote to anatomy, what to the hospital practice; where you should take notes, and where you need not do so. There are, however, some general suggestions, which I may venture to offer, without exceeding those bounds to which I wish that my observations should be restricted, and without taking on myself those duties which more properly belong to others.

The first effect usually produced on the mind of a medical student, is that of being bewildered by the number and variety of subjects to which his attention is directed. In one class-room he is instructed in chemistry; in another, in the *materia medica*. In one place, the structure of the human body is unravelled before him; and in another, he contemplates the interminable varieties of disease, and the methods which are adopted for their cure. He sees none of the relations by which these different investigations are combined together, so as to form one science. He has the opportunity of learning a great number of facts, but for the most part they are insulated, and independent of each other; he can reduce them to no order, and the want of a proper arrangement and classification makes the recollection of them difficult and uncertain. But this is not peculiar to medical students. The same difficulty occurs to every one, who enters for the first time on an extensive field of research; and they must indeed be very indolent, and very unfit for the business of life, who suffer themselves to be disheartened by it. Have patience for a while; keep your attention fixed on the matters which are brought before you, and after every lesson that you have received, or at the close of every day, endeavour to recollect what you have seen and heard; and in the course of a short time there will be an end of the confusion; the mist which there was before you will have passed away; where every thing had been obscure there will be a clear landscape; and the studies, which, when you were first initiated in them, were dry and irksome, will become interesting and agreeable. As you acquire a more extensive knowledge of individual facts it must necessarily happen that the relations which they bear to each other will become more distinctly developed. This, however, does not seem to be the whole explanation. I cannot well understand what I have observed to happen in myself, without supposing that

there is in the human mind a principle of order which operates without the mind itself being at the time conscious of it. You have been occupied with a particular investigation; you have accumulated a large store of facts; but that is all: after an interval of time, and without any further labour, or any addition to your stock of knowledge, you find all the facts which you have learned in their proper places, although you are not sensible of having made any effort for the purpose.

In the commencement of your studies, you will, at first, be altogether occupied in the acquirement of knowledge communicated to you by others. You will learn from lectures and from books what others have learned before you, and what is there taught you must take for granted to be true. A student may be very diligent and industrious, and yet go no farther than this through the whole period of his education. He may become an accomplished person; full of information; a walking Cyclopædia; and, at the end of his labours, may obtain the reputation of having passed through his examinations with the greatest credit. All this is as it should be, and those who think that to pass a creditable examination is the only object of their studies, will be quite satisfied with the result. But is it sufficient in reality? Are no qualifications required besides those, which are wanted for your examination? It is far otherwise, and no one will rise to be conspicuous in his profession, nor even to be very useful in it, whose ambition is thus limited. The descriptions of disease, and the rules of treatment, are simplified in lectures and in books; and if not so simplified, they could not be taught at all. But you will find hereafter, that disease is infinitely varied; that no two cases exactly, and in all respects, resemble each other, and that there are no exact precedents for the application of remedies. Every case that comes before you must be the subject of special thought and consideration; and, from the very beginning of your practice, although what is taught in lectures and books may render you great assistance, you will be thrown, in no small degree, on your own resources. There is no profession in which it is more essential that those engaged in it should cultivate the talent of observing, thinking, and reasoning for themselves, than it is in ours. The best part of every man's knowledge is that which he has acquired for himself, and which he can only to a limited extent communicate to others. You will spend your lives in endeavouring to add to your stores of information; you will, from day to day, obtain a clearer and deeper insight into the phenomena of disease; you will die at last, and three-fourths of your knowledge will die with you; and then others will run the same course. Our sciences are, indeed, progres-

sive; but how much more rapid would their progress be, if all the knowledge that experience gives, could be preserved. Now, these remarks are of practical importance to you all. You should begin to act upon them at an early period of your studies. Make out every thing relating to the structure of the body for yourselves. Do not altogether trust to what is told you in lectures and books, but make the knowledge your own by your own labours. Observe for yourselves the phenomena of disease, and the only way of doing this in an efficient manner is to take your own written notes of cases. I say, *your own* notes, for copying those taken by others, as far as the improvement of your own mind goes, is nearly useless; and when you have taken notes in the morning, write them out in the evening, and think of them, and compare them with one another, and converse on them with your fellow-students, and all this will render the investigation of disease a comparatively easy matter afterwards.

In these latter observations, I have anticipated some of those which I had intended to address especially to those among you who are on the point of offering themselves to the public as candidates for practice. It would be a fatal error for you to suppose that you have obtained the whole, or even any large portion of the knowledge which it is necessary for you to possess. You have not done much more than learn the way of learning. The most important part of your education remains;—that which you are to give yourselves, and to this there are no limits. Whatever number of years may have passed over your heads, however extended may be your experience, you will find that every day brings with it its own knowledge; you will still have something new to seek, some deficiencies to supply, some errors to be corrected. Whoever is sufficiently vain, or sufficiently idle, to rest contented, at any period of his life, with his present acquirements, will soon be left behind by his more diligent competitors. By the young practitioner, every case that he meets with, should be carefully studied; he should look at it on every side; and he should, on all occasions, assist his own inquiries by a reference to his notes of lectures and to books.

But it will rarely happen, that, in the beginning of a professional life, even the most diligent and the most successful person will be able to occupy the whole of his time with strictly professional pursuits; and the question must arise, "What is he to do with his leisure hours?" A most important question indeed it is; for the character, and the lot of the individual, must depend, in a very great degree, on the way in which such leisure hours are employed. If altogether devoted to what, dull, as they generally are, the world calls amusements, these do but

spoil the mind for better things ; and if you trust to such desultory occupations as accident may bring, the result will be no better. You will be the victims of melancholy and *ennui* ; an unreasonable despondency with respect to your future prospects will oppress your faculties, and deprive you of that spirit, and of those energies, which are absolutely necessary to your success. And these evils are easily avoided. How many branches of knowledge there are, which, if not directly, are indirectly useful in the study of pathology, medicine, and surgery ! and all general knowledge, whether of literature, or of moral or physical science, tends to expand the intellect, and to qualify it better for particular pursuits. There is no excuse for a young professional man, who does not devote some portion of his time to the general cultivation of his mind. His own profession have a right to expect it of him, and he owes it to his own character. Ours is no political profession. It is one belonging altogether to private life. Your place in society depends, not on your being mixed up with parties and factions ; not on circumstances external to yourselves, but on your own qualities ; you make it for yourselves. You wish, I conclude, to be received in society as being on a footing with well-educated gentlemen. But, for this purpose, you must be fitted to associate with them ; and this cannot be the case, if you know nothing of those matters, which are the general subject of conversation among them. The world care little about those distinctions, which, for the sake of a more convenient division of labour, we make among ourselves ; and a well-conducted and well-informed man will be just as well received in society if he belongs to one grade of the profession as if he belongs to another. It is very much to the discredit of the great medical institutions in this country, that, except in some few instances, they have not given even an indirect encouragement to the obtaining a good general education, and, in one instance, the legislature have actually done their best to throw an impediment in the way. I know that many, nevertheless, have not been without this advantage ; but they may improve themselves still further, and others may, in a great degree, make up for what they have lost, by a right disposal of their time in the early part of their practice.

It cannot be difficult for any one endowed with an ordinary degree of intelligence and curiosity, to fill up his vacant hours with pursuits that are no less interesting than useful. But your profession itself, from the moment that you are established as practitioners, will possess a new interest very different from that which belonged to it during the period of your pupillage. Hitherto you have been acting under the direction of others, and on their responsibility. Hereafter, you will have to act for yourselves, and

on your own responsibility. Whatever credit is to be obtained, it will be your own ; and, on the other hand, where blame is due, you may be sure that no one will volunteer to divide it with you. In every case that comes under your care, you will have to account to your own conscience for having done the very best that it was in your power to do for your patients' welfare : you will have to account also to others ; to your own immediate circle of friends and patients ; to society at large ; to all those whose favourable opinion of your character and conduct is necessary to your success in life. You will find yourselves surrounded by duties, responsibilities, and anxieties, which were unknown to you as students. He who has not a full sense of the responsibilities which it involves, is unfit for our profession ; and the anxieties of a professional life are but a wholesome stimulus to diligence and exertion. I say this, supposing them to be kept within reasonable bounds. You may allow your thoughts to dwell on subjects of anxiety until an entirely opposite effect is produced, and life is rendered miserable, and the mind enervated. Such a morbid sensibility is as mischievous on the one hand as a want of just sensibility is on the other. You must be careful to train the mind so that it may not fall into either of these extremes. Make every exertion to obtain knowledge, and to use it properly ; and then keep it in your recollection that there are bounds to human knowledge, and to human powers ; and that, in the exercise of our art, we cannot do all that is required of us ; for, if we could, pain and misery would be banished from the world, man would be immortal, and the order of the universe would be disturbed. Do not begin life with expecting too much of it. No one can avoid his share of its anxieties and difficulties. You will see persons who seem to enjoy such advantages of birth and fortune, that they can have no difficulties to contend with, and some one of you may be tempted to exclaim, "How much is their lot to be preferred to mine!" A moderate experience of the world will teach you not to be deceived by these false appearances. They have not your difficulties, but they have their own ; and those in whose path no real difficulties are placed, will make difficulties for themselves ; or, if they fail to do so, the dulness and monotony of their lives will be more intolerable than any of those difficulties which they may make, or which you find ready made for you. Real difficulties are much to be preferred to those which are artificial or imaginary ; for, of the former, the greater part may be overcome by talent and enterprise, while it is quite otherwise with the latter. Then, there is no greater happiness in life than that of surmounting difficulties ; and nothing will conduce more

than this to improve your intellectual faculties, or to make you satisfied with the situation which you have attained in life, whatever it may be.

To be prepared for difficulties; to meet them in a proper spirit; to make the necessary exertion when they occur; all this is absolutely necessary to your success, whatever your profession or your pursuit in life may be. No one can be useful to others, or obtain real credit for himself, who acts on any other rule of conduct. But it is more easy to lay down the rule than to follow it, unless the mind be disciplined for the purpose from the beginning. The natural tendency of mankind is to indolence; to shrink from difficulties; to try to evade them rather than to overcome them. Never yield to this disposition on small occasions; and thus you will acquire a habit which will enable you to do what is wanted on great occasions without any violent or painful effort. It is by neglecting their conduct in the smaller concerns of life, that so large a portion of mankind become unequal to the performance of their higher and more important duties. If you would know a man's character, look at what he does in trifles, and, for the most part, you will be able to form no inaccurate notion of what he would be in greater things.

I have heard the following anecdote of a distinguished individual who afterwards rose to the highest honours of the legal profession. For several years, in the early part of his life, he had been wholly without professional employment. One term went, and another came; but that which brought briefs to others brought none to him. Still he was always at his post, and, disappointed but not discouraged, he continued to labour, laying up stores of knowledge for his future use. At last, it happened that he was employed as a junior counsel in a cause of great importance. The evening before the cause was to come on in the court in which he professed to practise, the senior counsel, or (as he is technically called) his leader, was seized with a sudden illness. No one of the same standing could be found to supply his place; and late in the evening the solicitor went, probably unwillingly enough, to the junior counsel, and represented to him under what circumstances he was placed, and that he must trust to him alone. All the hours of the night were devoted to the task. The knowledge which the poor obscure student had acquired now turned to good account. On the following day he gained such credit that his reputation was established; and from this time his elevation was rapid. Now this may perhaps be regarded as an extreme case, but something like it must happen to every one who attains a high station afterwards. There are few so

indolent that they will not make an exertion for the sake of an immediate reward; but it is a poor spirit that can accomplish no more than this. The knowledge which you acquire to-day may not be wanted for the next twenty years. You may devote whole days and nights to study, and at the end of the year may not be aware that you have derived the smallest advantage from it. But you must persevere nevertheless; and you may do so in the full confidence that the reward will come at last. There is nothing in which the difference between man and man is more conspicuous than it is in this; that one is content to labour for the sake of what he may obtain at a more advanced period of his life, while another thinks that this is too long to wait, and looks only to the immediate result. At first, the former may seem not only to make no greater progress than the latter, but even to be the more stationary of the two. But wait, and you will find a mighty difference at last. You cannot judge from the first success of a professional person what his ultimate success will be; and this observation applies especially to those who contend for the greater prizes, not only in our profession, but in the majority of human pursuits.

A thorough determination to attain an object is the first step towards its attainment.

If you wish to advance yourselves in the way of life which you have chosen, you must persevere in one undeviating course, wandering neither to the right nor to the left, or making such excursions as you make into other regions of knowledge subservient to your main pursuit. What is called a life of pleasure is incompatible with a life of business; and those who have a more noble ambition, who love knowledge for its own sake, must learn to limit their ambition, and not waste their talents or their reputation by grasping at too much. Those who would excel in all things will excel in nothing. They may excite the wonder of the educated and uneducated vulgar; but those who are the best qualified to judge will detect their weakness, and smile at their superficial acquirements; and, after all their labour, they may die at last, and leave the world no better than it would have been if they had never existed.

And here I can conceive that some among you may say, "Is there anything which the medical profession can bestow, which will prove a compensation for the labour, the exertion, and the sacrifices which it entails upon us? Is it better to continue in it, or to turn aside to some other pursuit or employment? Indeed, it is well that this question should be thoroughly considered before it is too late; for, as far as I have seen of the world, nothing is more ruinous than that unsettled state of mind which

would lead you, when you are fairly embarked in one profession, to grow dissatisfied with it, and desert it for another. There are, I know, some remarkable instances in which the result was different; but it would be dangerous to quote these as precedents which you might safely follow, or to make the example of a peculiar genius, like that of Erskine, the foundation of a rule for ordinary men.

I know of no profession that is worthy of being pursued, which does not require as much exertion, as much labour, as many sacrifices, as that in which you are engaged; and I also know of none in which he who has the necessary qualifications is more sure of being rewarded for his labours. If it be your ambition to obtain political rank, or to have that sort of reputation which a political life affords, you will be disappointed; for, as I have already observed, our profession has nothing to do with politics. It belongs to private life; and the only other association which it has is that of science. There are few departments of either physical or moral science with which it is not, in a greater or less degree, connected; and there are some with which the connection is so intimate, that the study of them may be almost regarded as identical. The study of anatomy and physiology is a necessary preliminary to that of pathology; and the former cannot be understood by any one who has not some knowledge of the laws of mechanics and optics. Animal chemistry is daily becoming more essential to physiology, and is even beginning to illuminate some of the more obscure parts of the science of disease. You are to look, not to political rank, but to the rank of science. No other rank belonged to Newton or Cavendish, to Hunter or Davy; yet their names will live in distant ages; and they will be regarded as benefactors of the human race, when the greater number of their more noisy contemporaries, if remembered at all, are remembered without respect.

We are informed by his son-in-law and biographer, that, when Mr. Pott was seized with his last illness, he said, "My lamp is nearly extinguished: I hope that it has burned for the benefit of others." He addressed himself to his own family, and died on the following day; and, under such circumstances, it would be absurd to suppose that this was said merely with a view to produce an effect, or that these were any but his real and heartfelt sentiments. Undoubtedly it must be a great satisfaction at the close of life, to be able to look back on the years which are passed, and to feel that you have lived, not for yourselves alone, but that you have been useful to others. You may be assured, also, that the same feeling is a source of comfort and happiness at any

period of life. There is nothing in this world so good as usefulness. It binds your fellow-creatures to you, and you to them; it tends to the improvement of your own character; and it gives you a real importance in society much beyond what any artificial station can bestow. It is a great advantage to you, that the profession in which you are about to enter, if properly pursued, is pre-eminently useful. It has no other object; and you cannot do good to yourselves without having done good to others first. Thus it engenders good feelings and habits; and I know of no order in society who, taken as a whole, are more disinterested, or more ready to perform acts of kindness to others, than the members of the medical profession.

Usefulness is the best foundation of independence. There are some ways of life in which it is common for individuals to obtain unmerited advancement by the patronage of others. But you must be your own patrons. Your knowledge, your skill, your good character, will constitute your fortunes. Your dearest friends will feel that they are not justified in entrusting the lives and comfort of themselves and their families to your care, unless they have reason to believe that it is safe and prudent for them to do so, and that they can do nothing better; and so far, you are no more under an obligation to those who consult you than a landlord is under an obligation to the tenant of his house or land. Those who are well disposed towards you cannot help you unless you first help yourselves. But let me not be mistaken. It is well to be conscious that you are to rely on yourselves alone; and that even if you were base enough to cringe and stoop for the purpose of obtaining the favour of others, you could derive no permanent advantage from it. This is the independence which I mean; and not that proud and misanthropical independence which rejects the feeling of all obligations to others. Whoever gives you his good opinion, whatever his station in life may be, is, in some measure, to be considered as conferring an obligation on you, and deserves to be regarded by you with kindness in return. Mankind are bound to each other by mutually receiving and conferring benefits. You cannot live in the world, and, at the same time, live apart from it, and say, "I will owe no thanks to others; for whatever advantages I may obtain I will be indebted to myself alone." All those who do justice to your real or supposed merits have a claim on your gratitude. As others will lean upon you, so you must be content to lean upon them. On no other terms can you form a part of the great community of mankind.

There are some employments which bring those who are engaged in them in contact more especially with the bad qualities of

mankind; their pride, their arrogance, their selfishness, their want of principle. It is not so with your profession. All varieties of character will be thrown open to your view; but, nevertheless, you will see on the whole the better sides of human nature; much indeed of its weakness, much of its failings, much of what is wrong; but more of what is good, in it. Communicating, as you will probably do, with persons of all conditions, you will be led to estimate others according to their intrinsic qualities, and not according to those circumstances which are external to themselves: you will learn, that of the various classes of which society is composed, no one is preeminently good, or preeminently bad; and that the difference is merely this, that the vices and virtues of one class are not exactly the vices and virtues of another. You will have little sympathy with those prejudices which separate different classes from each other; which cause the poor to look with suspicion on the rich, and the rich to look down upon the poor; and while you cannot fail to perceive the great advantages which education gives, you will acknowledge, that, to be well educated, is not the necessary result of having the opportunity of education; that a bad education is worse than none at all; and that what are called the uneducated classes present many examples, not only of the highest religious and moral principles, but of superior intellect, and of minds stored with valuable knowledge.

All this is good for your own minds; but it is a still greater advantage to you, that a good moral character is not less necessary to your advancement in the medical profession than skill and knowledge. Nor is it merely a strict observance of the higher rules of morality that is required. You must feel and act as gentlemen. I can find no word so expressive of what I mean as this. But let there be no misunderstanding as to who is to be regarded as a gentleman. It is not he who is fashionable in his dress, expensive in his habits, fond of fine equipages, pushing himself into the society of those who are above himself in their worldly station, that is entitled to that appellation. It is he who sympathizes with others, and is careful not to hurt their feelings even on trifling occasions; who, in little things as well as in great, observes that simple but comprehensive maxim of our Christian faith, "Do unto others, as you would they should do unto you;" who, in his intercourse with society, assumes nothing which does not belong to him, and yet respects himself; this is the kind of gentleman which a medical practitioner should wish to be. Never pretend to know what cannot be known; make no promises which it is not probable that you will be able to fulfil: you

will not satisfy every one at the moment, for many require of our art that which our art cannot bestow; but you may look forward with confidence to the good opinion of the public, which time will bring as your reward, and to act otherwise is to put yourself on a level with charlatans and quacks.

To obtain such a competency as will place yourselves and your families above the reach of want, and enable you to enjoy such of the comforts and advantages of life as usually fall to the lot of persons in the same station with yourselves, is, undoubtedly, one of your first duties, and one of the principal objects to which your attention should be directed: but, nevertheless, let it never be forgotten that this forms but a part, and a small part, of professional success. If, indeed, money were the only object of life; if to enjoy the respect of others, and the approbation of your own conscience; to feel that you are doing some good in the world, and that your names will be held in esteem when you are gone out of it; if these things were to form no part of your ambition, then indeed you might possibly have your ambition gratified by pursuing a different course from that which I have pointed out. You might be unscrupulous in your promises; undertaking to heal the incurable; making much of trifling complaints for your own profit; claiming credit where none belongs to you; and you might try to advance yourself by what is often called a knowledge of mankind, or a knowledge of human nature. But how is that term misapplied! Knowledge of human nature indeed! This is the most difficult, the most interesting, the most useful science in which the mind of man can be engaged. Shakspeare knew human nature, as it were, by instinct. It has been the favourite study of the greatest men; of Bacon, of Addison, of Johnson. But of those who are commonly spoken of in the world as knowing human nature, the majority are merely cunning men, who have a keen perception of the weak points of other men's characters, and thus know how to turn the failings of those, who probably are superior to themselves in intellect, to their own account.

Generous feelings belong to youth, and I cannot suppose that there is a single individual present, who would not turn away with disgust from any advantages which were to be obtained by such means as these. Your future experience of the world, if you use it properly, will but confirm you in these sentiments; for you will discover that of those who strive to elevate themselves by unworthy artifices, it is only a very small proportion who obtain even that to which they are contented to aspire; and that the great majority are altogether disappointed, living to be the contempt of others, and especially

so of their own profession, and, for the most part, ending their days in wretchedness and poverty.

There is only one other subject to which, in concluding this address, I think it right to claim your attention. You have duties to perform among yourselves, one to another. There is no one among us who does not exercise an influence, to a greater or less extent, over those with whom he associates, while he is influenced by them in return. In whatever orbit a man moves, he carries others with him. If the vicious have their followers, those who set a bright example of honour and integrity have their followers also. In like manner, industry in one leads to industry in another, and the mind which is imbued with the love of knowledge cannot fail to communicate some portion of that holy inspiration to the minds of others. These, which are among the higher responsibilities of life, have begun with you already. The course which you individually may pursue, does not concern yourselves alone. While you are making your own characters, you will help to make the characters of others. Let this consideration be ever present to your thoughts. It will give you an increased interest in life. It will extend your sympathies with those around you; and it will afford you an additional stimulus to persevere in those honourable exertions, for which you will, at no great distance of time, be rewarded by the respect of the world, and esteem of your own profession.

POISONING WITH LABURNUM.

[THE following is extracted from a paper on this subject by Dr. Christison, in the last number of the Edin. Med. and Surg. Journal.]

A few months ago, I received for consultation the following singular case, which has since been made the subject of a trial at the last Inverness Circuit.

A lad, Hugh Gordon, 18 years of age, a farm-servant in the parish of Dornoch, in Ross-shire, was on bad terms with his fellow-servant, the cook, on account of some petty grievances, real or imaginary; and bethought him of punishing her by administering some substance which should cause vomiting or purging. On conversing with his acquaintances on the subject, one of them suggested to him for the purpose the "French-broom-bark;" by which name is understood, in Ross-

shire, the *Cytisus Laburnum*, the common laburnum-tree. And his informant added for his more particular instruction, that "he must mind how he cut the bark; for if he cut it off the tree from below upwards, it would make a vomit; if he should cut it downwards, it would make physic; and if he cut it across, it would kill." With these instructions, he cut the bark in the presence of a witness "for a vomit only," that is, from below upwards, and carried off a piece about one or two inches square.

The bark, in its dry state, was put into the cook's broth by Gordon, with the privity of another female servant, who witnessed the whole proceeding, and was aware of the lad's purpose; so that she became an accessory, and was charged as such by the law authorities. The two culprits partook of the same broth, but without this seasoning; and they sustained no harm. The cook, who remarked at the time "a strong peculiar taste in the broth, which it ought not to have had," soon became very ill, and in five minutes was attacked with violent vomiting. As the account of the symptoms was not taken till six months afterwards, when the cause of her illness was first discovered, the details are necessarily imperfect. It appears, however, that after the first attack of vomiting, which occurred at three in the afternoon, one day in the month of April of last year, the retching and vomiting continued incessantly throughout the whole evening, night, and subsequent day; that there was, at the same time, shivering, general pain in the belly, especially in the stomach, and such feebleness from the moment she first took ill, that she with difficulty walked to her bed; and that severe purging also occurred on the morning of the second day. It was some days before she recovered so far as to be able to resume her work. The sickness, vomiting, and purging, however, continued to recur in some degree daily; she complained of pains around the abdomen; she rapidly fell off in looks, and flesh, and strength; at Whitsuntide, about six weeks after she first took ill, she was forced to give up service: and her complaints went on without any intermission, except in degree, till November, when she was visited for the first time, by a physician, Dr. Ross, who was sent on the part of

the law authorities to investigate the particulars of the case. Dr. Ross found her labouring under symptoms of marked gastro-intestinal irritation, such as vomiting, especially after food, pains in the abdomen, increased by pressure, diarrhoea, with tenesmus and slightly sanguinolent stools, flatulent distension of the belly, and the like. She had likewise great debility, impaired appetite, hurried and laborious respiration, a rather frequent and easily excitable pulse, strong bellows sound over the roots of the large vessels at the heart, a pale countenance, bloodless lips, and a pale, glazed tongue. Dr. Ross considered her at that time in a highly dangerous state.

When consulted about this case a month afterwards, I was led, by the unusual occurrence of so protracted an illness after poisoning with a vegetable substance, which must have been in all probability discharged, to suggest the propriety of a minute examination of every organ, with a view to ascertain whether there might not be some organic disease of one or other of the great abdominal viscera, with whose chronic disorders it is well known that the alimentary canal often remarkably sympathizes. But after a careful examination, no sign of organic disease could be detected in any other organ except the alimentary canal; and Dr. Ross's diagnosis in this respect was confirmed by the woman's eventual recovery; which took place very slowly, however, and was not altogether complete at the time of the lad's trial in April last. Considering, therefore, the whole progress of the case, together with the fact that the woman enjoyed excellent, and even robust health, previous to the administration of the laburnum bark, no other view, in my opinion, could be taken of the whole circumstances than that if the bark caused the first symptoms, it also occasioned all the subsequent illness.

I am thus particular in endeavouring to trace the whole details and their reciprocal connection, because the woman's illness, in all its circumstances, is somewhat different from what might have been expected from such a poison. Let me now advert to the question, whether such effects as were here observed may be clearly referred to the agency of the substance alleged to have been administered.

That the substance given was laburnum bark, there can be no doubt. One of the culprit's companions saw him cut it; he himself confessed he administered what he was seen to cut: and a portion of the bark, with a few pods, taken from one of a row of the same species, from one or another of which the bark employed by him had been obtained, was sent to me at my request, for identification, and proved to be the undoubted produce of the *Cytisus laburnum*.

Now, as to the possibility of this substance producing the effects observed in the case, it may in the first instance be remarked,—and the fact is not a little singular,—that I have not hitherto been able to find a single observation, in any toxicological author, on the effects of the bark of the laburnum, however well known they seem to be to the common people of the northern Highlands.

In the absence of direct information on the subject, it is fair to presume that the bark may cause vomiting and purging, since these effects are ascribed both to the leaves, and the young pods, and the seeds of the tree. For it is well known, that in many natural families of plants, and, among the rest, in the *leguminosæ*, to which the laburnum-tree belongs, there is a close agreement between the leaves and the bark in their action on the human body. Still, as there exist exceptions to this general law, the inference founded on it is but presumptive; and it needs scarcely to be observed, that in medico-legal toxicology, presumptions, while they may lead to evidence, cannot be admitted as evidence themselves. It became necessary, therefore, to ascertain the properties of laburnum bark, by direct experiments on the lower animals.

Dr. Ross, at my suggestion, made some experiments of the kind, of which the following were the result. A teaspoonful of the powder of dry laburnum bark was administered to a cat. Soon afterwards it was seen to writhe apparently in great pain; but in a short time it vomited violently, and thus cleared out its stomach. It looked languid and dejected for the rest of the day, and then quickly recovered. Sixty-nine grains of the same powder were then administered in porridge to a collie dog. In ten minutes it whined

and moaned, then violently vomited all its food, and soon got well. On a second occasion twenty grains were found sufficient to act upon this animal as an efficacious emetic. These experiments show that the bark of laburnum is an irritant, and one too of no mean energy. But the facility with which the dog and cat evacuate the stomach renders it impossible to ascertain in their instances the poisonous effects of the bark, in all their details, by the simple method of administration with the food. Neither does it appear to me that the method which consists in confining the poison in the alimentary canal by a ligature on the gullet, is here very applicable; because the circumstances in the case which an experimental inquiry was intended to elucidate, are such as to require the uncombined effects of the poison to be observed for a longer period than it is possible to do after the operation of tying the gullet.

In undertaking an experimental investigation on my own part, therefore, it appeared advisable to try in the first instance the effects of the bark on the rabbit; as this animal does not discharge irritating substances from its stomach by vomiting. I accordingly administered to a full-grown rabbit, by means of a catheter introduced into the stomach, an ounce of infusion of laburnum bark, containing the active matter of 62 grains of the bark; and that there might be no question as to the identity of the substance employed, the bark made use of was that sent to me from Ross-shire, as having been taken from one of the trees in the row where the culprit Gordon got his bark. The result, I must confess, astonished me. In the course of ten minutes the rabbit began to look quickly from one side to another, as if uncertain in which direction to go, then twitched back its head twice or thrice, and instantly fell on its side in violent tetanic convulsions, with alternating emprostotonos and opisthotonos so energetic, that its body bounded with great force upon the side up and down the room. Suddenly, however, all movement ceased, respiration was at an end, the whole muscles became quite flaccid, no sign of sensation could be elicited; death in short had taken place, and that within two minutes and a half after the poison was injected into the stomach. The body

was opened in two minutes more, and the heart was found gorged, but contracting with some force, and capable of contraction under stimuli. The stomach was found filled with green pulp soaked with the infusion; the muscles were contractile. No morbid appearance was visible anywhere.

This single experiment left no doubt that laburnum bark is a poison of unexpected energy; but the effects of course associate it with narcotics, not with the irritant poisons.

Dr. Ross subsequently repeated this experiment, and found that one rabbit died in half an hour, and another in three quarters of an hour, after small doses of the infusion were injected into the stomach with a catheter; and that a third rabbit also speedily died after eating greens impregnated with the infusion. In all these instances convulsions were the leading symptoms produced.

Other occupations have prevented me from following out farther this inquiry into the properties of the laburnum bark. A more complete inquiry would doubtless present results of no little interest. The facts now brought forward are in the meantime sufficient to prove that this poison is one of exceeding energy; that it is a narcotico-acrid poison; that in large doses, yet still in quantities of no great amount, it acts with violence and celerity as a narcotic; and that in small doses it is a dangerous irritant, acting with force both upon the stomach and intestines. It needs scarce be added that facts of so much importance, and which relate to a substance so common and so easily obtained by every one, ought to be more generally known than at present.

CASE OF

STRANGULATED CONGENITAL HERNIA REDUCED EN MASSE.

To the Editor of the Medical Gazette.

SIR,

I SEND to you the subjoined case of strangulated congenital hernia reduced *en masse*, relieved by operation, hoping that you will favour it with insertion in one of your early numbers. I lay it before the profession with a strong impression upon my mind, that many lives have heretofore been sacrificed by the

neglect of a proper course of proceeding in such cases. It appears to me therefore important that the attention of persons in active practice should be drawn to the subject to which it refers, in a more pointed manner than has hitherto been done in this country by writers on hernia.

It was with this view that last winter I forwarded a few cases with remarks to the Medical and Chirurgical Society, which have been honoured with a place in its Transactions recently published. I wish the present case to be considered as an appendix to them, for by so considering it, it will be unnecessary to append any comments further than to state that the means of diagnosis by local examination pointed out in my observations upon the cases read before the Society, were satisfactory in this, to the extent in which they were available under the peculiar circumstances of a congenital hernia so reduced.

The subject of the case was by profession an engraver, æt. 39 years, married; father of eight children, and generally a healthy man. About nine o'clock in the evening of the 6th of October, 1843, he called in his way home at Mr. Dawson's surgery, Islington, complaining of severe pain in the abdomen and sickness. He stated that he had suffered a similar pain on the 4th, which had disturbed his rest during the night, but that it had passed off in the morning, leaving him easy throughout the 5th, on which day there had been a motion from the bowels.

Upon the present occasion the pain had returned with increased violence, and had existed for about two hours. The pulse was not more than 70 in a minute, and there were not any febrile symptoms present. Pressure could be borne over the whole abdomen without any increase of pain. Mr. Dawson being aware of the existence of a hernia, instituted inquiries concerning it, but learnt that it was not down, and had not been down for a long time previous. An active aperient was administered, and the abdomen ordered to be fomented.

About half past eleven Mr. Dawson was called to the patient's house, the pain of the abdomen having much increased. He learnt that since his previous interview the hernia had descended, and now formed a tumor about the size of an egg, hard, but not very

painful. The reduction of this by the taxis was accomplished in three or four minutes, by the use of moderate pressure and with little pain, after which the patient expressed himself relieved. An ounce of castor oil combined with ten drops of tincture of opium was administered, and retained on the stomach without sickness.

When seen on the morning of the 7th, it was found that he had passed a restless night, and suffered much pain and tenderness over the whole abdomen, but not more at one part than another, nor more on the right side than on the left. There had not been any action of the bowels, and the sickness had returned. The countenance was much depressed. Sixteen ounces of blood were taken from the arm, followed by faintness, and calomel combined with opium was given.

At this period Mr. Dawson requested my attendance in consultation. I saw the patient about twelve o'clock. He was then suffering great pain. The countenance was anxious, the pulse was weak and depressed, the bowels had not acted from the medicines administered, and there had been a frequent rejection of the contents of the stomach by vomiting. I learnt that he had been the subject of inguinal hernia on the right side for some years, for which he had worn a truss during the last two.

On inspection of the groin I found that the right testicle had not descended from the abdomen, and that the neighbourhood of the rings was free from the external appearance of tumor, but there was on comparison found a very slight fulness on the right side more than on the left. When the hand was pressed over the internal ring, a small tumor could be obscurely felt; but not painful to the touch, the principal seat of pain being the left side and pit of the stomach.

The tumor alluded to was supposed to be formed by the undescended testicle, which supposition was subsequently found to be correct.

It was remarked that the external inguinal ring (which was large and admitted the introduction of the finger), was not occupied by any structures passing through it, such as might be presumed to pass through it provided a hernial sac remained in the part after its contents were reduced. The in-

ference was therefore drawn, that the sac had been reduced with its contents, and the suspicion arose, from the persistence of symptoms of intestinal obstruction, that those contents were in a state of strangulation, and constituted the kind of case known as reduction *en masse*. Under this impression, the patient was requested to get out of bed, to cough and strain, and use some exertion to produce a re-descent of the hernia. The appearance of a small flaccid tumor at the external ring was the result, but not painful, and easily returnable by a very slight pressure with the finger. The act of standing caused considerable pain over the whole region of the groin, from which the patient became faint, and in consequence was replaced in bed. Although the case was one the nature of which I fully suspected, I thought it not advisable to proceed to an exploration by operation instantly; but preferred waiting for a few hours the effect of some opening medicine which we further ordered to be administered. I determined, however, to have recourse to an operation at our next meeting, provided the bowels should not previously be relieved.

I was again summoned to attend before the arrival of the time appointed (six hours). The symptoms had become much increased in severity, the countenance was very anxious, and the prostration very great. Vomiting was frequent, and a most distressing hiccough annoyed the patient almost without intermission. The pain at the pit of the stomach had increased to agony, and the abdomen was tense and tympanitic. The groin was in the same state as at noon, but the whole neighbourhood was entirely free from pain, even when pressed on firmly with the hand.

An operation was proposed, and performed without delay.

The operation.—The patient's legs being brought over the side of the bed, his shoulders were supported by pillows. This position, by rendering the abdominal muscles more tense, caused the tumor previously mentioned to become more prominent, but it did not exhibit the tension and resistance common to strangulated hernial tumors. It, however, became the guide to my proceedings. An incision between three and four inches in extent being made over

it, by a little dissection it was brought into view, and ascertained to contain fluid. By a puncture of the containing sac the fluid was let out, and, upon its escape, every appearance of tumor vanished. The opening being enlarged sufficiently, a finger was introduced through the sac into the inguinal canal, as far as the internal ring, in which situation a rounded body was detected, which eventually proved to be the testicle, but rather small, and which, I doubt not, formed the tumor felt on pressure over the internal ring in the first examination of the part.

On introducing the finger beyond this, a second rounded body was felt, lying deeply within the abdominal parietes, and extending as far as the finger would reach. The sac being more completely laid open, the testicle was readily brought into view; but to expose the second rounded body was a matter of some difficulty, and was eventually accomplished by forcibly pulling the divided portion of the sac, by which means the remainder of the sac was drawn out from the abdomen, together with its contents. This latter consisted of a knuckle of intestine, about four inches in length, and somewhat dark in colour. It was found to be strictured by the neck of the sac; the stricture before it was drawn out from the abdomen, being barely capable of being reached with the finger. There was considerable tendency of the sac, with its contents, to recede again within the abdomen on the remission of the force used for its withdrawal, and it became necessary to be held by an assistant, that the division of the stricture might be accomplished without the danger consequent upon an attempt to effect it while it was lying deeply within the parietes. In this I was assisted by Mr. Lyndall, who was present with Mr. Dawson. After the division of the stricture the intestine was easily returned into the general peritoneal cavity, followed by the finger for the purpose of ascertaining that it was entirely free from constriction. The return was almost immediately followed by relief to the distressing hiccough and intense pain of the pit of the stomach.

The wound was closed by two sutures, and the patient placed in bed. There were not any medicines administered.

Oct. 8th.—The patient is much better, and the pain of the abdomen has considerably abated. The pulse is tranquil, and the countenance much improved. The skin is free from febrile heat, and the bowels have been opened nine times without the aid of medicine.

Ordered a little beef-tea and a rice-pudding.

9th.—Abdomen slightly tympanitic and painful about the stomach. In other respects going on well.

Ordered ʒij. of Epsom Salts in ʒj. of Infusion of Gentian every two hours until the bowels are opened.

10th.—There have been two or three motions, and the tympanitic state and pain of the abdomen have passed away. The wound was dressed to-day, and found united through a considerable extent by adhesion.

16th.—The progress has been uniformly satisfactory. Wound nearly healed. The patient says he is quite well. On this day I took my leave.—I am, sir,

Your obedient servant,

J. LUKE.

REMARKS ON FATTY URINE.

By GOLDING BIRD, A.M. M.D.

Assistant Physician to, and Lecturer on Materia Medica at, Guy's Hospital.

(For the *London Medical Gazette*.)

CASES of fatty urine are exceedingly unfrequent; and no very accurate account of this curious pathological condition of the renal secretion has been published since Dr. Prout drew attention to the subject.

I am indebted for the opportunity of investigating a well-marked case of this affection to the kindness of Mr. Montagne Gossett, in whose practice it occurred. This case was peculiarly interesting on account of several curious anomalies it presented, as well as from its affording an opportunity of correcting the account generally given of the microscopic characters of urine containing fat.

The first specimens of the urine from the patient to which I have referred were given to me on April 14th of this year, with an inquiry as to their nature:

one specimen was of sp. gr. 1.018, somewhat paler than usual, and was perfectly transparent, with the exception of a slight mucous cloud. The other specimen, stated to have been passed some hours before the former, resembled milk in colour and general appearance, and was quite free from any urinous odour: it was faintly acid, of sp. gr. 1.020: the addition of either nitric or hydrochloric acid produced a considerable curdling. By repose, a cream formed on the surface of the urine, forming a layer $\frac{1}{10}$ th the thickness of the whole volume of fluid. When a drop of this milky urine was placed under the microscope, no only globules could be seen when examined with an excellent object-glass of $\frac{1}{4}$ th inch focus, by Powell; the turbidity appears to depend upon an immense number of particles, so minute that under a magnifying power of 800 diameter they resembled mere points.

I confess that I could not help suspecting that some addition had been made to the urine by the patient after its being passed; an idea that at first gained some support from the fact, that when the bladder was emptied by means of the catheter, the urine was found to be quite transparent and healthy.

On April 22d, I saw Mrs. T—— in bed; she was an extremely fat, flabby woman, about 35 years of age, the mother of several children. She expressed herself as quite well with regard to her general health, and only complained of the occasional milky state of the urine as possibly indicative of some threatening ailment. She stated to me that for several years she had been accustomed to pass milky urine, especially during part of her pregnancies. On several occasions the urine, although not milky, had gelatinised on cooling so as to assume the form of the receiving vessel like so much ordinary jelly. The appearance of the milky urine was exceedingly capricious, sometimes being constant for weeks together, and then disappearing for some time. She could trace no apparent connection between its appearance and any obvious exciting cause: it bore no evident relation to the quality, quantity, or hours of her meals, nor to the periods of menstruation. The only general rule she had observed regarding its appearance was that it most frequently appeared when she

first voided urine on rising from bed, and hence she fancied it was produced by lying on her back all night. It had become most frequent in its appearance since she had begun to grow fat.

My visit was made about 2 P.M.; Mrs. T— had not risen except to pass water since the preceding evening. Three specimens of urine were shewn me as having been passed since an early hour in the morning.

The first specimen was like ordinary urine: contained an abundance of pinkish urate of ammonia, which disappeared by heat: it was acid, and not coagulable; contained no albumen.

The second specimen was as pale as water, subacid, and, on heating it, clouds formed in it from the coagulation of albumen.

The third specimen was of a healthy amber colour; it appeared natural, and was free from albumen.

The examination of these specimens certainly gave no satisfactory explanation of the nature of the milky urine she had previously passed, and she declared that this was the first occasion on which she had failed to pass that kind of urine for some weeks. I introduced a catheter into the bladder, and a pint of fluid escaped, possessing the colour, colour, and general appearance, of hot milk and water; in fact, having none of the physical characters of urine.

The specimen thus obtained was of sp. gr. 1010, slightly acid; by repose a cream-like layer formed on its surface, leaving the lower portion of the fluid nearly transparent. I may remark that Mrs. T— had not partaken of any food since breakfast.

This milk-like urine presented the following chemical characters.

A. When exposed to heat, a large and tremulous coagulum of albumen formed, becoming firmer and more solid on raising the temperature to ebullition.

B. About four ounces of the urine were agitated with half an ounce of pure ether, and the mixture set aside in a carefully closed bottle. On the following day, the mixture had lost all its opacity, and presented three well-defined layers. The lowest, forming the great bulk of the urine, was transparent, and consisted of urine deprived of the ingredients which had produced its previous opacity. On the surface

of this rested a perfectly transparent and tolerably firm coagulum of fibrin, about a quarter of an inch thick, of a pale yellowish colour. The superior layer consisted of an ethereal solution of fatty matter; this fluid was of a fine golden yellow colour.

C. The ethereal solution was decanted and allowed to evaporate spontaneously: a large proportion of yellow fat, closely resembling butter in colour and odour, was left. It differed from some specimens of fatter matter obtained by an analogous process from milky serum of blood, in not presenting any tendency to crystallize. This yellow fat readily fused by heat into a perfectly transparent oil, which slowly solidified by cooling, and it has undergone no change by keeping up to the present period.

D. A portion of the urine left to itself for some time underwent no further change than the formation of a thin creamy layer on its surface; not the slightest tendency to the formation of a fibrous coagulum appeared.

E. A portion of the milky fluid was evaporated at a boiling temperature to dryness, and digested with hot water. The fluid was filtered, and after concentration treated with nitric acid, when crystals of nitrate of urea slowly formed.

I carefully examined the urine under the microscope, but not the slightest appearance of oil globules, blood-discs, or pus granules, could be detected; the opacity appearing as in the first specimen given me by Mr. Gossett to depend upon the presence of particles so minute as to present no defined form; appearing like mere irregular points when examined with a linear power of 800 under an excellent achromatic microscope. The result of this examination is completely opposed to the few statements recorded by continental observers on the optical characters of fatty urine. Thus M. L'Heritier* has stated that oily globules can always be detected in fatty urine; and a similar remark is made by Franz Simon† of Berlin. The latter has, indeed, stated that he has met with three varieties of fatty urine; one in which

* *Traité de Chimie Pathologique*, Paris, 1812, p. 180.

† *Physiologische und Pathologische Anthropologie*. Berlin, 1842. Bd. 2, S. 386. A translation of this very useful and elaborate system of pathological chemistry into our language will shortly appear from the pen of Dr. Day. A work of this kind has long been a desideratum.

the fat is merely diffused through it, and collects on its surface by repose, as in the cases recorded by Dr. Elliotson; the other in which the fat exists combined with albumen; and a third in which the fatty matter existed with casein as an emulsion, forming in fact true milky urine. In all these Simon states that fat-globules could be seen by the microscope.

So far as my own observations have extended I have never met with true milky urine, but I may remark that when milk is added to urine the oil-globules are easily seen by the microscope, even for a long period, quite unchanged.

In the urine passed by Mrs. T—, there can be no question but that the fat existed with the fibrin as an emulsion, so minutely broken up, and perhaps combined with the latter, as to lose its characteristic microscopic characters. The analytic power displayed by the ether was peculiarly interesting: by merely dissolving out the fat it left the albuminous matter in a position capable of concreting into a transparent fibrous clot by repose, and by rendering the urine transparent, at once demonstrated the cause of its previous opacity. The presence of the fat probably mechanically prevented the formation of a coagulum of fibrin until it was removed by the solvent power of the ether.

A case somewhat similar to the present has been recorded by Bizio*: he compared the fat to butter: it is to be regretted, however, that he did not make any microscopic examination of the urine. M. Rayer† has stated that in all the cases of fatty urine which have fallen under his notice, albumen has invariably been present. He further remarks, that chylous urine contains globules like those of blood, readily distinguishable from pus granules by microscopic examination.

To what class can the urine of Mrs. T— be referred? In its general properties it approaches closely to what has been termed chylous urine by Dr. Prout and others, but the absence of fat-globules at present points out a characteristic difference, if the microscopic appearances of this form of urine have been correctly recorded.

I can view this case in no other light than that of one in which a great tendency to the development of adipose matter existed, and an excess of fat, not capable of being otherwise appropriated, escaped by the kidneys in the form of an emulsion with the spontaneously coagulable albumen of the blood (*fibrin*): still the occasional occurrence of this pathological state of the secretion, alternating with healthy and even albuminous urine, is at least exceedingly remarkable, and presents anomalies which at present admit of no satisfactory solution.

Cases of this kind are so extremely rare, that it would be an important point for every practitioner who meets with a case of milk-like urine, in which the opacity does not disappear by heat or nitric acid, and in which purulent matter is not suspected to be present, to submit it to a careful microscopic investigation to ascertain in what state the fatty matter really exists in the urine, and whether it alternates with albuminous urine, independently of the presence of organic disease.

I have since my visit to this patient heard from her but once, and then she appeared in good health; still, however, passing the milk-like urine at irregular periods.

ON SULPHATE OF POTASS.

To the Editor of the Medical Gazette.

SIR,

I BEG to submit for the consideration of the profession, that the injurious effects of sulphate of potass may be entirely traced to irritation, caused by the spiculæ of undissolved salt. This opinion was suggested partly by the announcement of Chevallier, that on a post-mortem examination of the stomach and intestines of an individual whose death had been caused by this salt, portions of undissolved salt were found in the stomach and intestines; and at such points inflammation of the mucous membrane was especially remarked. On this suggestion I washed some of the powdered sulphate of potass of the shops, and thus removed that portion of the salt which existed in a more minute state of division. Under the

* Schweigger's Journal für Chemie, B. xi. s. 246.

† Traité des Maladies des Reins, p. 155, t. 1.

microscope, the undissolved portion was found to consist of exceedingly sharp-pointed acicular fragments, really formidable in appearance; some of these, when attached to a point by wax, were capable of wounding the skin of the arm like glass.

A dose of two drachms of this coarser powder caused much more uneasiness than four drachms of the salt precipitated by spirit of wine from an aqueous solution; indeed, the effect of the latter was as rapid as sulphate of magnesia, whereas the former not only caused some considerable pain, but its effects were felt for two days after the dose had been taken.

It was mentioned by a gentleman, at the meeting of the Pharmaceutical Society held on the evening of the 11th inst., that he had remarked the solubility of sulphate of potass was increased by sesqui-carbonate of soda; that ten grains of sesqui-carbonate of soda were sufficient to render readily soluble two drachms of the sulphate of potass; and upon the same grounds as James obtained the various explanations why a fish weighed more when dead than when alive, so the society was informed this might arise from double decomposition! Every chemist will smile when he is informed that sulphate of potass might be decomposed by carbonate of soda; but every chemist may not be at the pains to test so simple an assertion as that sulphate of potass is more soluble in a solution of carbonate of soda than in distilled water: therefore I may perhaps spare some conjecturing by stating that such is not the fact, and that, except as regards the variations of temperature, which have a very slight effect indeed, sesqui-carbonate of soda, in the quantities above stated, and even when increased to thrice the above quantity, does not render the liquid capable of dissolving more potass.

To return, I beg, then, to suggest to practitioners that, when sulphate of potass is administered to patients, where the stomach is exceedingly irritable, in a dry form, that the salt be prepared in a minute state of division by precipitation; or if in solution, that a sufficient quantity of water (three ounces of water to two drachms of sulphate) be employed for its perfect solution. By this practice the salt may lose its character as a permanent laxa-

tive, but the serious effects narrated in your last will, in my humble opinion, be avoided.—I am, sir,

Your obedient servant,
G. M. MOWBRAY.

MATICO.

To the Editor of the Medical Gazette.

SIR,

YOUR publication of Oct. 6th contains a report of some cases, by Dr. H. Lane, of Lancaster, shewing the efficacy of the infusion of matico as an injection in leucorrhœa, &c.; but, in publishing these cases, it is somewhat surprising that Dr. Lane should have omitted all mention of the individual (Dr. Jeffreys, of this town) to whose zeal and perseverance, in despite of many obstacles, we are indebted for its introduction, whereas it might be inferred from Dr. Lane's communication that *he* was the first person to make trial of its internal use, as he merely alludes to the paper of Dr. Monro, of Dundee, respecting its external application.

The history of the introduction of the matico to the knowledge of British practitioners is this:—A friend of Dr. Jeffreys, on his return from South America in 1837, gave him a specimen of this plant, stating its common use as a styptic in that country, and describing the occurrence by which its efficacy was accidentally discovered.

Dr. Jeffreys published a short account of it in the *Lancet* of Jan. 5, 1839.

He subsequently, at considerable expense, procured a large supply, which he distributed gratuitously to a great number of medical practitioners, as well as to various hospitals and public institutions, amongst which was the Lancaster Infirmary and Dispensary, and he had some correspondence with Mr. C. Ricketts, the house-surgeon, in 1841.

Dr. Lane does not state how the matico came into his possession, but it is not improbable that it formed a part of that supplied to Mr. Ricketts by Dr. Jeffreys.

The letter of Dr. Monro to which Dr. Lane refers is expressly addressed to Dr. Jeffreys.

If your readers will consult the last vol. (Vol. XI.) of the *Transactions of*

the Provincial Association, they will find a paper on matico by Dr. Jeffreys, with an engraving copied from the *Flora Peruviana*. In this paper, several cases are recorded by different practitioners of the efficacy of the infusion *internally* in dysentery, menorrhagia, leucorrhœa, &c., so that it is rather singular that Dr. Lane should state that he was not aware that it had hitherto been employed internally.

The application of it as an injection in leucorrhœa has, I think, not been previously recorded.

The cases of Dr. Lane add confirmation to the value of matico as a remedial agent: and it was for that very object that Dr. Jeffreys distributed so large a quantity through various parts of the kingdom. I scarcely know whether it is worth while to address you on this subject, but I consider it due to Dr. Jeffreys that all notice of the merit, which he may fairly claim for its introduction, should not be either accidentally or intentionally omitted.

I am, sir,

Your obedient servant,

R. W. SCOTT, M.D.

Liverpool, Oct. 19, 1843.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Lectures on the Eruptive Fevers, delivered at St. Thomas's Hospital, in January 1843. By GEORGE GREGORY, M.D. &c. 1843.

DR. GREGORY has been long known to the profession as a most industrious and useful labourer in the department of our art to which these lectures refer. His connection for many years with the Small-Pox Hospital has given him great opportunities, and the papers he has at various times published shew that they have not been thrown away upon him. The present differs in one respect from any of the Doctor's former productions, namely, as to the style, which is here conversational rather than didactic; a remark which we by no means intend should convey any unfavourable impression: indeed, the language appears to us remarkably unaffected and agreeable.

The characters and affinities of the

eruptive fevers are first explained; the mutual relation of these diseases to each other are exhibited, and the importance of the skin as a portion of the animal frame demonstrated. The greater exanthemata are those more particularly enumerated, and the influence they have upon human life is clearly demonstrated: by this it appears that upon an average nearly 40,000 die annually of one or other of the exanthemata in England, and about 5000 in London alone, giving an average of about 11 per cent. of the total mortality from all causes: four diseases thus producing one-ninth of the total mortality of Great Britain, and probably of Europe.

The following are the circumstances which mark the general characters of the exanthemata. 1. The presence and course of the constitutional disturbance. 2. The local affection. 3. The law of universal susceptibility. 4. Their non-recurrence. 5. Their being contagious. 6. Their being epidemic. These are severally made the subject of discussion, and some interesting observations are offered on each; after which the principles which ought to guide us in the general management of this class of diseases are clearly and satisfactorily pointed out. In this part of his work the author very properly urges that the great object of our treatment in the exanthemata ought to be rather to guard against those “congestions and superadded affections” by which they are frequently accompanied, than attempting specific remedies against the original malady itself.

The first exanthem spoken of individually, is small-pox; a disease of which Dr. Gregory has, we presume, seen more than has fallen to the lot of any other practitioner of the present day; but as we have frequently had occasion to allude to his papers as they have from time to time appeared, we shall now confine ourselves to a few points of interest.

Among these, the extent to which the fluids become implicated in small-pox cannot fail to excite attention, and a very curious illustration of it is given by Dr. Gregory. The miasm, as it were, poisons the blood, altering its properties and power of coagulating in a remarkable manner. Among other instances of this the author mentions that he was last year called into con-

sultation with Dr. L. Stewart, regarding a lady in small-pox, whose whole body was of the colour of indigo, so that he took her at first for an African. She conversed with our author quite tranquilly but a few hours before her death, "proving that the nervous system is not necessarily, nor is it even usually, implicated in the petechial form of small-pox."

In the cases of adult females, Dr. Gregory states, that when thus attacked menorrhagia is almost always present, and if they be pregnant they almost invariably miscarry, the foetus dying in utero. This is what used to be called black small-pox by the older writers.

Ophthalmia is a very common accompaniment of small-pox; but it is a mistake to suppose (as is often done) that this arises from the formation of pustules on the cornea and conjunctiva. There is no specific inflammation of the eye in small-pox, but the ophthalmia so destructive of vision is a sequela of the disease. It frequently sets in about the tenth day, and runs its course so rapidly that the eye is destroyed within forty-eight hours.

The chest also is frequently affected; but the abdomen is peculiarly exempt from inflammation in small-pox: thus we are told the idea of any thing like pustules being found on the mucous membrane of the stomach or bowels is erroneous, the appearances in reality being "in all respects" the same as are met with in typhus fever.

The whole human race, with very few exceptions, is susceptible of this disease, and the inhabitants of different regions seem to be in this respect on an equal footing. To this general rule there are several exceptions, and persons have been known to go through life without ever taking the disease, though frequently exposed to it. Again, some persons appear unsusceptible of the disease at one time, and yet take it at another. Dr. Gregory gives an example of this. A lady residing at Salisbury was inoculated for small-pox in 1804, at the age of 83, and took it. She had brought up a large family, many of whom had passed through small-pox, and been attended by her, without her becoming affected with the disease. It has been said that an exemption from the disease prevails in particular families, but Dr. Gregory states that this idea is entirely without foundation.

That small-pox may occur a second time in the same individual is a well-known fact; but our author states it to be much less frequent than is supposed. "At the Small-Pox Hospital very few present themselves who affirm that they have previously undergone small-pox; and of the few who do, but a very small portion can stand the test of a rigid scrutiny." Louis XV. of France, is said to have died of a second attack of small-pox, but Dr. Gregory (who has examined the details carefully,) is of opinion that the first attack was not really variola.

The power of medical treatment over small-pox is by no means so striking as in inflammation; nevertheless, remedies exert a certain degree of influence upon the disease, and the things to be attempted are thus enumerated.

1. To moderate the violence of febrile excitement whenever we meet with it.

2. To check and relieve local determinations of blood, at whatever period of the disease they arise.

3. To support the powers of the system when they flag, either from the malignity of the poison or the long continuance of the disorder.

4. To combat, by appropriate means, concomitant disease.

One of the most interesting questions certainly connected with the treatment of small-pox relates to blood-letting. On this point Dr. Gregory makes the following observations:—

"Some writers, in their zeal for blood-letting, have tried to persuade themselves that it is the only measure which can be relied on to lessen confluence, and to prevent the development of pustules in the mucous membrane of the throat and trachea. This opinion is altogether erroneous. Bleeding has no effect on the quantity of eruption, whether cutaneous or mucous. The most confluent eruption has succeeded to the most vigorous employment of the lancet. To bleed, therefore, merely because small-pox is anticipated, with the view, thereby, of preventing confluence, is uselessly to expend that power which will be required for the repair of injury to the surface. You will keep these general principles before you, and take care that in your efforts to diminish internal congestion you do not materially impair constitutional power.

"If the stomach during the initiatory

fever, remains very irritable, rejecting everything that is taken, even the saline effervescing draughts with laudanum, which you will naturally feel disposed to try, I recommend you to apply mustard poultices to the epigastrium and to the feet, and to promote eruption by the pediluvium.

Again: if the circulation at this period be languid, if the pulse be small and feeble, the skin pale, and the extremities cold: if the patient lies on his back, sunk and exhausted, let him have immediately warm brandy and water, cover him with bedclothes, apply mustard poultices to the centre and extremities of the circulating system, and give thirty drops of laudanum, to be repeated in four hours, if necessary. This cordial plan of treatment must often be continued for several days, when the eruptive risus is accompanied with depression, and nature appears so obviously unequal to the effort."

In ordinary cases, the great object is to lessen the patient's suffering, without interrupting the process of pustulation; and, if there be nothing particular, a few saline draughts, and a little castor-oil, so as to keep the bowels free, are all that is required. The petechial form of the disease admits, he thinks, of no essential relief from medicine. "The loss of a little blood from the arm has appeared to me more effectual than any other measure." In all cases a warm bath is advisable before the patient again mixes in society.

Where, in the process of the secondary fever, apoplexy, peripneumony, or pleurisy comes on, blood may be taken freely; but in erysipelas, bark and wine are sometimes required. In ophthalmia (one of the most serious evils which follows small-pox), it is sometimes necessary to sacrifice the eye to save the patient's life—the state of whose system prohibits the requisite depletions.

In regard to the eruption itself, Dr. Gregory informs us that benefit is frequently derived from covering the surface with dry powder, such as starch; while fomentations and poultices are the only local means of any service in the abscesses and erythematous inflammations which sometimes attend the stage of secondary fever.

All the plans hitherto suggested for preventing pitting, have, in our author's hands, proved unavailing.

On the subject of inoculation, the opinions of our author are somewhat different from those entertained by most persons, and we shall conclude this part of our analysis by quoting his opinions in his own words.

"Since the introduction of vaccination, it has been the fashion to decry inoculation, and to impute to it mischief of which it was not guilty. The great objection made to inoculation, and that which recently induced Parliament to abolish it altogether, under heavy penalties, was, that it disseminated the virus, and multiplied the foci of contagion. Dr. Watkinson and Dr. Schwenke, in 1777, and more recently, Dr. Adams, broke the force of this argument, by pointing out how important a part epidemic influence plays in the diffusion of variola. Had they lived in our times, how strongly would they have fortified their arguments! We saw, in 1838, an epidemic small-pox raging in London, where inoculation had long been discontinued. The admissions into the Small-Pox Hospital in that year exceeded those of 1781 and of 1796. Inoculation was abolished throughout England and Wales in 1840, and the act has been most rigidly enforced; yet, during the last two years, small-pox has visited every county of England.

Sir Gilbert Blane has attempted to prove by statistics the evils of inoculation. He has shewn that the proportion which the mortality by small-pox in London bore to the general mortality, increased during the last century from 78 to 94 per thousand. But various considerations serve to weaken the force of this argument. If, for instance, we divide the last ninety years of the 18th century into three periods, we shall find that the recorded deaths by small-pox were as follow:—1711 to 1740 (when there was no inoculation), 55,383; 1741 to 1770 (when inoculation was coming into general use), 63,308; 1771 to 1800 (when inoculation was almost universal,) the deaths were only 57,268: so that, by this shewing, inoculation diminished the mortality by 8115 lives!

"Statistics are very useful, and deservedly carry great weight with them; but they may be enlisted, with a little management, on both sides of an argument.

"One subject only remains for our

consideration, and that is, the question, whether any circumstances would still warrant us in recommending inoculation on scientific principles? Concurring most cordially in opinion that the practice of inoculation by *unqualified* persons ought to have been put down) not in 1840, but forty years before that) by stringent legislative enactments, I still remain of opinion, that under several circumstances it is the duty of a medical man to recommend inoculation. These circumstances do not, indeed, often occur; but the legislature would hardly wish to control and fetter, even in a single case, the deliberate judgment of a physician, acting for the benefit of his patient. I will name to you four of these cases:—

1. When a person has been found, from peculiarity of habit, unsusceptible of vaccination.
2. When new sources of vaccine lymph are introduced, and it becomes of importance to ascertain that the new virus is efficient.
3. When young persons (between the ages of ten and twenty), vaccinated in early life, are proceeding as cadets to India.
4. When small-pox unexpectedly breaks out in a country district, at a time when (even with the facilities of a penny post) vaccine virus is not to be obtained.

“Other cases, equally strong, might be put; but what I have said will probably suffice to show that a clause (duly guarded against abuse) permitting qualified medical practitioners to inoculate under circumstances of urgency, would have been an useful addition to the Vaccination Extension Bill. That it was not so added was no fault of mine.”

Our author next proceeds to give an account of measles, scarlatina, and erysipelas. But these we pass by, in order to arrive at vaccination. Into the history of this, which is elaborately detailed, we shall not enter, but go at once to the practical points: these relate to the selection of lymph, the manner of making the incisions, and the number of them which is required to secure the full prophylactic effect. On these points we shall quote Dr. Gregory's opinions.

“The proper time at which lymph may be taken so as to obtain it in the most efficient state for propagating the disease, has also been a subject of discussion. Some have objected to the

employment of very early lymph, others have scruples in taking lymph after the first appearance of areola, and all parties have concurred in condemning the use of lymph taken on or after the tenth day. The facts bearing on this question are as follows. The younger the lymph is, the greater is its intensity. The lymph of a fifth-day vesicle, when it can be obtained, never fails. It is, however, equally powerful up to the eighth day, at which time it is also most abundant. After the formation of areola, the true specific of cow-pox becomes mixed with variable proportions of serum, the result of common inflammation, and diluted lymph is always less efficacious than the concentrated virus. After the tenth day, the lymph becomes mucilaginous, and scarcely fluid, in which state it is not at all to be depended on. Out of a dozen incisions made with such viscid lymph, not more than one will prove effective. The scabs of cow-pox, ground to powder, and moistened with lukewarm water to the consistence of mucilage, will sometimes reproduce the disease in all its purity, a satisfactory proof that the alteration which the lymph undergoes in its progress to maturity is not of a specific kind, liable to influence the result of the subsequent vaccination, but simply dilution. Experiments with diluted lymph were formerly made by Dr. Adams, at the Small-Pox Hospital, and have since been repeated in France by M. Bousquet, and it is ascertained that effective vaccination may be thus produced.

“2. The second subject for our consideration is the mode of making the incision, so as to ensure the best and most certain results. Failure in the operation is always harassing to the friends, and is often made the pretext for delays dangerous to the child. Some surgeons use a sharp, others prefer a blunt lancet. Some consider it necessary to make the wound very superficial, others go deeper, and are careless whether much or little blood follows the incision. A few operators scarify the skin in numerous places, in preference to making incisions. I know very well that, provided the lymph be good, it matters little in what way the virus be applied, but the most uniformly successful mode is the following. Let the lancet be exceedingly sharp.

It should penetrate the corion to a considerable depth. The notion that the subsequent effusion of blood will wash out the virus, and thus defeat our intention, is quite imaginary and groundless. Provided that a genuine lymph of due intensity has once come in contact with the absorbing surface of the cutis vera, the rest is immaterial. The vessels of the part have received the specific stimulus, and nothing can prevent the advance of the disorder but some constitutional cause. In making the incision, the skin should be held perfectly tense between the forefinger and thumb of the left hand. The lancet should be held in a slanting position, and the incision made from above downwards.

"3. I would recommend that with lymph of ordinary intensity five vesicles should be raised, and that these should be at such distances from each other as not to become confluent in their advance to maturation.

"Vaccine lymph should always be used in a fluid state, and direct from the arm, wherever practicable, for it is a very delicate secretion, and very slight changes in it are capable of materially altering its qualities. Lymph which has been retained fluid for four or five days is very apt to occasion that irritable vesicle which I described to you as the most frequent of all the anomalous appearances. Dr. Gulliver has lately been occupied in attempts to discover, by means of the microscope, what is the exact change which vaccine lymph undergoes by keeping, and which gives to it this noxious quality. His observations have not hitherto yielded any decisive results, but enough has appeared to warrant further and more extended inquiries.

"When lymph fresh from the arm cannot be obtained, other means must be had recourse to. Vaccine virus may be preserved fluid and effective for two or three days in small bottles, with projecting ground stoppers, fitted to retain the matter. It may be preserved for a like time in small capillary tubes having a central bulb. This is the mode usually adopted in France for the transmission of vaccine lymph to the provinces, and which proves very effectual; but if you attempt in this manner to transmit lymph to the East or West Indies, you fail utterly.

"You must all have seen what are

called ivory points. These, when well armed and carefully dried, are very effective. They will retain their activity in this climate for many months, and they are found to be the most certain mode of sending lymph to our colonies. Some practitioners prefer glasses to points, but they are less certain. The employment of scabs for the propagation of cow-pox was first recommended by Mr. Bryce, of Edinburgh, in 1802. It is a very excellent mode of transmitting vaccine matter to distant countries, but some nicety is required in operating with scabs, which experience alone can teach."

The pathology and results of vaccination are next detailed, under which he discusses the ideas entertained by Jenner and others as to cow-pox and small-pox being modifications of each other. He then refers to the experiments and reasonings of other writers, but concludes by giving it as his own opinion that the disorders, though allied, are not identical. He afterwards proceeds to point out, as distinguishing marks, that the one (cow-pox) produces no eruption or constitutional disturbance—that it is not contagious, or rather that it "throws off no contagious emanations", and that it is communicated from one man to another in the same degree of intensity, whereas in small-pox the severity of the disease is diminished by inoculation. Again, with respect to the local characters—in small-pox the pustule is *accuminated*; the corion sloughs, and the adjacent cellular membrane becomes implicated. The arcola, too, differs, being circular in cow-pox and irregular in variola. He thus concludes this part of the subject:—

"On all these grounds I demur to the theory of identity, and hold that small-pox and cow-pox are antagonist affections—that cow-pox, instead of being, as Dr. Baron maintains, of a variolous, is, in fact, of an *anti-variolous* nature—that it alters and modifies the human constitution so as to render some individuals wholly, others partially, and for a time, unsusceptible of small-pox.

"I have gone into this detail, because the doctrine of identity is now very generally received throughout this country, and I cannot but think it has been hastily adopted. The difficulties into which such a doctrine leads us

will be made very manifest when we have investigated the facts regarding post-vaccine small-pox."

We find next an interesting account of the statistics of small-pox after vaccination, but we have, on former occasions, laid our author's opinions on these points before our readers, and therefore omit them here. On the subject of re-vaccination he is in favour of its adoption, because it gives little pain or inconvenience, yet he doubts whether it adds anything material to the security of the individual.

But we must have done. Time and space alike warn us to bring our observations to a close, and we take leave of our author with regret, strongly recommending his work to all who desire to possess the best information on the subject of the Exanthemata.

MEDICAL GAZETTE.

Friday, October 27, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ELECTIONS.

It would be paradoxical to assert that we are not a very representative or elective people; but to the middling classes the theory of our constitution has so thoroughly assured the right of being represented, that the majority do not much care to inquire whether they are so or not, or to exercise an undoubted privilege, though any attempt to deny their right would be angrily resented.

It is true that the business of elections in political matters is carried on from various motives with a good deal of spirit, though the franchise does not seem to be exercised in a very sober or deliberative manner, and many voters, no doubt, are rather driven to the hustings by laborious personal instigation than attracted by a desire to carry out their political opinions. In municipal contests it is much the same—in

more private matters, such as charities, benefit societies, and others, in which each member is supposed to take a warm interest in the institution which he voluntarily supports, the difficulty of inducing governors to vote is often very great; and although in a spirited contest a large number of quiet people may be dragged to the poll in the train of the different candidates, it is evident that most of these are conscripts, not volunteers; while the large number who are permanently marked in every canvassing list as never voting, is too remarkable to escape notice, and proves how determined in many is the state of indifference.

The truth seems to be, that we trust very much to the results of common sense in the details as well as in the principles of our private and public governments, and moreover that this trust arises from each of us being conscious of possessing an average share of this valuable quality himself, and therefore readily giving credit for an equal or greater amount of it in others. In like manner common honesty, which usually accompanies common sense, induces its possessor to give others credit for at least as great a share of it as he has himself, and when we read the letters of competitors for offices of trust, we generally suppose each man to be capable and willing to discharge the duties of the office which he seeks; the somewhat high-flown language of the candidates, and of those who recommend them, being considered as mere *phrases de convention*, no more intended or likely to deceive than the "most obedient humble" service tendered at the foot of the letter.

Englishmen, we said, give each other credit for common sense and common honesty, and so they vote with indifference, or under the influence of personal regard, or they do not vote at all: they pay their subscriptions, and

trust the details of management to the few who prove their zeal by the habitual devotion of their time and attention, as well as of their purse, to the object in question.

But uncommon sense, and uncommon honesty, excite something like indignation towards those who pretend to them. We require strong proofs of qualities so much above the average—so much above our own habitual estimation of ourselves, even when exalted for the time by the challenge it has received. Instinctive repugnance to such assumption either excites us strenuously to oppose the attack on our self-esteem, or is appeased by the proofs of real superiority which are called forth by resistance.

This opposition, then, to large pretensions, is a most wholesome element in promoting an average, though somewhat supine, performance of the elective functions; and is, at the same time, a valuable index to the general qualities of the individuals concerned.

Particular seasons and circumstances, however, interrupt for a time this quiet belief in ourselves and others, favour the exaggerated claims of pretenders, and give a feverish stimulus to the pulse of society.

It is to be hoped that by the wholesome working of the new charter of the College of Surgeons, the elective functions of one division of our brethren may be kept in a healthy state; neither torpid from total disuse, nor irritated by over excitement.

QUACKERY.

It is curious to observe the circumstances which make people the prey of quacks. There must be first a strong desire for some apparent or real good—health for the sick, bread for the hungry, rest for the overworked, employment and pay for the unemployed.

There must be a belief in our own powers to attain these advantages if the proper means were brought within our reach, and a further belief in our power to discriminate the persons and the methods most likely to secure them. This belief in our own sagacity in choosing the best means of relief is the predominant quality in the dupes of quackery: it produces a morbid state of the elective function, which, like other functional disturbance, if long continued, is apt to induce organic disease—and a very troublesome disease it is to the sufferer and those about him. A few weeks ago we met with Father Matthew in a swamp in Bermondsey. If ever dram-drinking were excusable, it was in such a place. But the ruddy, good-humoured apostle of temperance preached away *de bon cœur* to fit audience, though few. As one batch of dram-drinkers after another took the pledge, it was impossible not to wish they might keep it. But just behind the scaffold of the water-drinkers was a gallant Captain, well known to all frequenters of public meetings, who was holding forth on the virtues of his inhaler, and promulgating his very remarkable theories of disease and political economy. In substance they are these: that the nerves are hollow tubes; that there is no such thing as a solid in the body; that the great *fomes mali*, the exciting cause of all modern maladies, is white vitriol prepared from human and other bones, for the bakers and brewers, and put into the beer by the orders of government, to brutalize the people, and render necessary the employment of soldiers and policemen. Either in spite of, or in consequence of this instructive lecture, many persons cheerfully underwent the process of inhaling the smoke of a wax candle, and listened with much attention to the advice of the lecturer; and a young man who begged them not to believe in the

sorry delusions of a well-known lunatic, narrowly escaped rough handling, being denounced as a spy and emissary of the doctors.

Now surely the term "debility in action," which has been ingeniously employed to express a morbid state of the bodily functions, is no less applicable to the mental state of these patients. Their elective functions, exceedingly feebly performed in general, were excited by the doctrines and the arguments of the tea-totallers who had come amongst them, and so, with full confidence in the sagacity with which they had chosen a drinking creed, they proceeded forthwith to choose their medical adviser as above described. The Captain, by the bye, shewed much shrewdness and frankness in saying: "I always follow Paddy Matthew, for he brings out the sick, the lame, and the lazy."

Yet what in these poor people seemed so incredibly silly, that the whole scene was a kind of anachronism in the 19th century, a *tableau-moyen agiste* revived in the metropolis of England, may be found every day amongst the wealthiest of our countrymen, as those can testify who have to deal with the sick, the lame, and the lazy in high places.

About the same time we met with a highly intelligent peer, who consults the most eminent men in the capital for form's sake, and without the slightest belief in their powers of relieving him, but who was expecting with impatience the arrival of a doctor from Vienna, whom he intended to retain in England, at a liberal salary, while superintending a course of a secret remedy for gout, which he determined to undergo.

It is not one of the least evils of quackery, that its pretensions are not always wholly unfounded; nay, the resources of legitimate medicine are sometimes recruited from its ranks. The

London Pharmacopœia retains the paste of Ward, and the powder of Dover, who flourished in the reign of Queen Anne. The men were of unequal merit, their nostrums were alike valuable, and in the lines of Pope their names are embalmed together.

"See Ward by battered beaux invited over,
And desperate misery lay hold on Dover."

VITAL STATISTICS OF SHEFFIELD.

To the Editor of the Medical Gazette.

SIR,

IN your journal of September the 8th, we observe some extracts from a work by Dr. Holland, entitled "The Vital Statistics of Sheffield," and we think the comments that follow are not very complimentary to the feelings of a public man (than whom none is more deserving of the respect of the working classes of Sheffield.) Giving you credit, which we do, for purity of intention, we cannot help thinking that you have fallen into the same error in respect to his character and motives as some other writers have done. Justice and gratitude, therefore, impel us to say a few words on those heads treated of in your remarks. In the first place we beg to say, that it is not our intention to make any lengthened comments on those trades which are in union, nor on the advantages resulting from the same, as we take precisely the same view of the subject as Dr. Holland, and like him may perhaps be accused of entertaining Malthusian doctrines.

The silver and plated trade is spoken of, but in a manner that leaves but little room for argument. It is very true that the workmen in this branch have felt but little of commercial depression for at least twenty years. Previous to that period, however, they were in a very depressed state, owing to the numerous surplus hands which had been created, the result of a disorganized condition. In consequence of this many were driven upon the parish funds, while the far greater part that was employed, was only partially so, which rendered it impossible for them (a few cases excepted) to eke out anything like a comfortable livelihood. We have certainly no criterion as to whether you are favourable to trades' associations or otherwise; the vague manner they are spoken of prevents us from forming any correct conclusions concerning your opinions. We

shall make but few remarks upon what is said upon the saw-makers, the edge-tool makers, the file trade, and other branches in union, which are named by you; nor shall we stop to make any inquiries about "black-smiths drinking more than they reason" (?) nor why it is that forgers of Sheffield should have such big occiputs, but low retreating foreheads! We are too much identified with the welfare of trades' unions to trouble our heads with the above matters. Our business would be, to prove, if desired, that as far as Sheffield is concerned, her artisans who have been the longest in union have had less fluctuations in their respective trades, more of the comforts of life, while the greatest harmony exists betwixt them and their employers. Something is stated about the edge-tool makers, which implies a defect in respect "to how long a period the men are in work," and for what length of time they have received a certain statement of wages. These are questions we are not prepared to solve; we can only say, they have been in union for a long time, and as a consequence have had fewer fluctuations than almost any branch of artisans in this town.

No writer ever displayed more anxiety to ascertain facts than Dr. Holland: every statement that he has made relative to the circumstances and education of the artisans of Sheffield can be borne out by the strongest evidence; and they form a striking contrast to those trades that are named in the journal as not being in union. We shall now offer a few remarks upon the most important of them. We begin with the spring-knife makers, who, we know for a fact, are badly remunerated and badly educated. A few of the superior workmen may earn the specified sums, viz. from 30s. to 40s., but the far greater part of them cannot earn above 12s. or 14s. per week, labouring as they do thirteen or fourteen hours per day, and in many cases not above 8s. or 9s. At the time Dr. Holland wrote the above work, this branch was not in union, nor had it been for a number of years, which accounts for the setting up of little masters among them, no laws existing to restrain them. That these little masters have inflicted a great injury upon the trade there can be no doubt. The table-knife hfters are placed upon the same footing in respect to condition and circumstances, and they and the spring-knife makers have a far greater proportion of hands than is to be found in any two trades in Sheffield; and painful to relate, a far greater number, as compared with other trades, are to be found on the parish books.

We now come to a most important branch, the fork grinders, an ill-fated class of men, as indeed other classes of that body of men

called grinders are. The appalling rate of mortality among fork grinders, which is commented on, is confirmed by their own printed statements. Some fault, we perceive, is found with Dr. Holland for not giving a statement of their wages: we will attempt to supply the deficiency. We have it upon authority on which we can place the utmost reliance, that the average wages of the men, assuming them to have plenty of employment, will not exceed 15s. or 16s. per week; from this sum 5s. or 6s. must be deducted weekly for wheel-room and cost of tools, leaving them about 10s. clear money. This is the remuneration of a useful class of artisans, whose occupation is so destructive to the human constitution, that, according to the language of the late Dr. Younge, of Sheffield, "none but the worst of felons ought to work at it." It is asked, and we hope humanely, "Can nothing be done for the fork grinders?" We say at once that something might and ought to be done, not only for them, but for other grinders who are similarly situated. The substitution of wet stones, which you suggest, for dry ones, is not practicable, or the trial would have been made long since. Every fork grinder would ridicule the attempt; but assuming it possible, we fear it would only mitigate and not remove the evil, a gaseous effluvia arising even in wet grinding from the particles of metal and stone. Yet even then, one part of their trade—we mean the finishing work—would have to be done on glaziers, in which process a dry powder is used. There are other grinding branches, as the scissor and razor grinders, who work upon dry and wet stones, yet the mortality in the two trades is nearly as among fork grinders, and the remuneration for their labour is very little if any better. In our opinion the best method of bettering their condition, and prolonging their lives, would be by an act of Parliament, to do away with cast metal cutlery; to force every manufacturer to strike his own name upon the articles which he makes; to compel proprietors of grinding wheels (which is urged by Dr. Holland) to ventilate them, which might be done by a cheap and simple process, and this would be a sure means of prolonging the lives of grinders generally. We are sure that a more disinterested advocate for such a measure than Dr. Holland could not possibly be found.

To enumerate all the miseries of the aforementioned artisans would almost fill a volume: a large portion of them, we are sorry to say, have been produced by their own folly. Instead of limiting the supply of hands in a ratio with the demand for labour, which ought to have been done,

they have gone on step by step increasing them, and their miserable condition has been augmented in the same proportion. This fact speaks loudly for itself in all the disorganized trades of Sheffield. We will, for example, cite the razor grinders. In the year 1810 the number of adult workmen was 96; in 1814, 124; in 1826, 162; in 1832, 188; in 1837, 228; in 1842, 275; in 1843, 300.

The minors in this unfortunate branch have increased in the same ratio; the consequence is, the demand for their labour has been diminished, and the prices have gradually been lowered. Thus a combination of circumstances has had such influence over this class of artisans, that the far greater part of them are a miserable set of men, stunted in growth, attenuated in their forms, presenting cadaverous and care-worn countenances, which abundantly prove the dire influence of the trade on the one hand, and very little of the comforts of life possessed on the other; in a word, of a body of men whose appearance denotes that they are destined for a premature grave. We ask, in the language of the man whose powerful advocacy of the rights of labour has entwined himself around our best affections, "Is this a picture which the philanthropist can contemplate with indifference? Is it in harmony with the growth of luxuries, the boasted diffusion of intelligence, and the spread of Christian principles?" Suffer us further to ask, does not the unfortunate condition of the above important class of human beings call for some legislative enactment on their behalf? You take Dr. Holland to task in respect to his sentiments on the amount of "religious instruction and education in our locality;" we certainly coincide with him in opinion, that the education imparted by Sunday-schools is insufficient, and of a superficial character; yet we, in common with many others, do not regret the loss of the late ministerial measure, as we think it was too bigoted and exclusive in its views, and therefore more calculated to be a bone of contention than to afford any permanent benefit. But if Dr. Holland asks for more schools, we do not agree with you in opinion, viz. that he might contribute the "profits of a work" containing elaborate and extensive researches, and much varied information, the execution of which must have cost him immense labour and considerable money. "The labourer is worthy of his hire," and whatever profit or advantage may accrue to him from it he has a right, consistently with the eternal principles of justice and equity, to dispose of that profit and advantage as he may think proper. If we are to have more education (and we are

advocates for a system as liberal and comprehensive in its character as can possibly be framed) we would suggest one that ought to emanate from the legislature rather different from that of Sir James Graham's. One of the Acts of the late government will not be easily erased from our memory; we mean the £20,000,000 granted to a body of monopolists who were already sufficiently gorged with wealth, and even luxury, in order that they might be induced to let go their hold of that impious and execrable traffic, black slaves. In alluding to this subject, we can and do most freely accord our meed of praise to the eloquent appeals that have been made, both in and out of Parliament, in their behalf, though, after all, it is but one-sided humanity. We are among those who detest slavery and tyranny in every shape and form, and we regret to say that we can see too many instances of it in this mis-called happy land, but particularly in our own locality. There are numerous artisans in Sheffield whose condition and circumstances can be proved to be no better than that of the African slaves in their worst state. To prove this we will only name one or two facts out of a multitude. In Sheffield, a single man (and there are great numbers on the parish) receives about 2s. 6d. per week, part of which is paid in bread. The scale of the married man is, if anything, worse, taking his family into consideration. The scale was originally 3s. for a single man, but the Guardians have recently thought proper to reduce it 6d., and that of the married man 1s., part of which sum is paid in bread, and this is often of a bad quality. For this they are condemned to heavy task-work every day, and in many cases to wheel barrows containing about 16 stones of rubbish, 14 pounds to the stone. No wonder, then, that the poor creatures, existing as they do upon such a miserable pittance, should sink under the load, as they have frequently done, while others have been hurried off rapidly to premature graves. Yet this is but a small sample of the many miseries that are inflicted upon our artisans, owing to the working of the Poor-Law Amendment Act,—a law so inhuman in its operation, and so callous to all the finer feelings of human nature, as would never be attempted to be inflicted on the black slaves by the worst portion of their owners. Their own interests would teach them, that, to perform their labour daily, slaves must be fed.

We shall now close this part of the subject by pressing upon those philanthropists who have said so much about African slavery, and likewise those who entertain liberal sentiments respecting education, the necessity of urging government to do something to amend the

physical and mental condition of myriads of white slaves at home. We think it would be no more than an act of justice, if half of the £800,000 that is paid to the owners of black slaves annually out of the taxes, and which they might very well spare, were applied to the white slaves of this country: this would be one means of answering the end required, and one which would render the government deservedly popular. We should extend our remarks far beyond the limits of a letter, were we to give full scope to our feelings upon the above subject. It is now, however, high time to say a few more words respecting Dr. Holland, who it appears is represented to be rather uncharitable towards the sick, "in a pamphlet he published four years ago." Assuming this to be a fact, what then? We do not hold the Doctor to be infallible, he is as much the creature of circumstances as any other man, and it is quite certain that at the time he wrote his pamphlet Sheffield was in a far better state in respect to the condition of its artisans than at present. This being the fact, there would be fewer cases of real want in regard to medical charity than now. If we were to enumerate all the charitable acts, and others of the greatest utility, that have been performed by him, and without the least ostentatious parade, we might name a long list. No man in Sheffield ever displayed more sympathy for grinders than he has done. Not long since he wrote a pamphlet in favour of the fork grinders, which made a powerful impression on the wealthy and influential classes, and this was the means of getting this unfortunate class of men betwixt two and three hundred pounds. So strongly was the public mind impressed in their favour, that it was their own fault they were not benefitted to double the amount. Subsequent to that period he has written pamphlets in favour of the pen-knife and razor grinders, which, like the one named, produced a powerful impression, and which ought to be in the hands of every artisan. As to the sufferings of grinders, the result of their occupation, we always find him ready to alleviate them, and in many cases he has succeeded. We equally find him the strenuous and powerful advocate of the rights of labour in all meetings or assemblages of various classes of artisans. He is ever ready to attend to offer his counsel and assistance, to warn them of danger, and to point out their true interest, not caring about his own ease or interest. These, and innumerable acts of kindness, he has performed to various individuals, without ever receiving a farthing advantage in return, or expecting to do so. Actions like these in our opinion far outweigh any objectionable sentiments he may entertain on medical charities which may have emanated

from his pen, and will not diminish an iota of that respect we entertain towards him, and which justice impels us to say is no more than his due. We shall now close this lengthy epistle, and request, as a particular favour, that it may be inserted in the next number of your widely circulating journal, whose pages are devoted to one of the most important branches of science that can possibly occupy the human mind. As a ground for urging this request, we hope it will be borne in mind that Dr. Holland has been spoken of in a manner that is not quite congenial to our feelings. A desire to do justice to him, as well as to point out means whereby a very important class of the community might be benefitted, has induced us to indite the preceding remarks. In conclusion we again respectfully request the insertion of them, and by so doing you will greatly oblige the delegates of the associated trades in Sheffield.—I am, sir,

Your very obedient servant,

JOHN DRURY, *Secretary.*

Sheffield, September 25, 1843,

POISONING WITH SULPHATE OF POTASS.

[Some observations have been made on this subject in a letter published in the *Times*, in which reference was inaccurately made to this journal; we therefore insert the following answer, which was transmitted to the journal above named.—ED. GAZ.]

SIR,

In the *Times* of to-day there appears a communication, signed by "A Surgeon," which is distinguished by two faults; it is both disingenuous and inaccurate—disingenuous, because your correspondent's remarks in reference to the *MEDICAL GAZETTE* omit all notice of "*six cases of poisoning by sulphate of potass*," inserted in the number for October 13th, your correspondent's letter being dated on the 15th; sadly inaccurate, because he states that "*arsenic, zinc, or copper, may, during the process of manufacturing nitric acid, be readily transferred, either as a whole or a part, to the residual sulphate of potass, thus contaminating it with a most dangerous poison*;" and further, "A Surgeon" adds, what is most untrue, "that this statement is no idle theory, but is sustained by direct experiment." Indeed, sir, but this is an idle theory, and has been refuted by my direct experiments. A chemist will need but the following detail to recognize at once the truth of my assertion, but which assertion I have verified by experiment.

With a view to remove the whole of the nitric acid from nitrate of potass, the manu-

facturer uses a proportion of sulphuric acid sufficient to form an acid—or bisulphate, strictly speaking a mixture of sulphate and bisulphate of potass; heat, and this approaches to dull redness, is applied to drive off the whole of the nitric acid: now, should the normal sulphuric acid have been contaminated with arsenic, the heat here applied would and *does* volatilize it; further, the subsequent neutralization of the residue with carbonate of potassa, and crystallization of the salt, which is somewhat insoluble, would also leave in the mother liquor any arseniate of potass, should any arsenic have been added intentionally; a further guarantee that, in the process of manufacture usually adopted, on account of its low cost, there is no risk of contamination with arsenic.

Commercial oil of vitriol, I may venture to say, does not contain arsenic now. During the time of the sulphur monopoly, chemists were driven to prepare it from iron pyrites; and it was then ascertained that occasionally a little arsenic was derived from this source. Its admirable purity and lowness of cost have rendered it sought by all continental nations as the best that can be procured, but the above circumstance is now dragged in to shield every crime, and explain every difficulty, where sulphuric acid or sulphates are brought in question.

This question will doubtless be solved at the trial, since I have reason to know that the Messrs. Watt, as well as myself, have tested sulphate of potass “taken from the same jar,” identical with that used by the party charged with the crime of murder; and if any benefit of a doubt can be afforded, the Messrs. W. will advance it. For my own part, although I have an opinion, it will not be communicated, so far as regards this point, until the trial is over, having no wish to enlighten juries unless by conferring a benefit on those most deeply interested. The prudence of your correspondent in withholding his signature deserves all the praise he may have anticipated from his communication; indeed, I should have hesitated in submitting these remarks, so entirely counter, and as he himself will I doubt not grant, yet so strictly accurate when submitted to the test of direct experiment, if it had involved the dissolution of the chemistry of perhaps a talented member of the profession.—I am, sir,

Your obedient servant,

A DRUG-VENDOR.

P.S. I enclose my card withal.

To the Editor of the Medical Gazette.

SIR,

FROM your remarks on the late inquest, you do not appear to be aware that several cases

of poisoning by sulphate of potass have appeared in the foreign journals. The only notices of these cases to which I can now refer you, are in the *Pharmaceutical Journal* for September, and the *Chemist* for August, in the present year. M. Moritz ascribes the poisonous effects of the salt to the presence of *sulphate of zinc*; others to *arsenic*, derived from the arseniferous pyrites from which sulphuric acid is now commonly procured. The question is one which demands, and will doubtless receive, a prompt and careful investigation.—I am, sir,

Your obedient servant

H. B.

Oct. 9, 1843.

P.S.—Dr. Pereira remarks that large doses are apt to produce sickness in children; but he does not appear to suspect that this effect is the result of any impurity in the salt.

HEMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

If the following hint be deemed worthy of a place in your valuable journal, you will oblige me by inserting it.

A STUDENT.

Oct. 17, 1843.

Some months ago there was described, in a number of the *MEDICAL GAZETTE*, a simple, easy, and efficacious method of treating epistaxis; of its efficacy I can speak highly, as I have on several occasions put an immediate stop to profuse hæmorrhage from the nose by adopting that plan. The treatment consists simply in making the patient hold up both arms above his head, when the bleeding will be found soon to cease.

Might not the same plan be pursued in cases of alarming hæmorrhage, that occurs in some persons, after the extraction of a tooth?

MARISCHAL COLLEGE AND UNIVERSITY, ABERDEEN.

REGULATIONS FOR GRANTING MEDICAL DEGREES.

Curriculum.

I.—FOUR years of attendance on Medical Classes, of which one year may be passed at any recognised Medical School; but three, at least, must be passed in a University, including one, at least, in this University. The attendance, in each year, to embrace not fewer than two Medical Classes of six months,

with two of three months each. But it will be held equivalent to *one* of four years of such attendance in a University, 1st, in a Master of Arts, to have attended one Medical Class while passing through the Curriculum of Arts; or, 2dly, in any Student, to have attended a Medical Class, in each of two years, along with the Classes in the Curriculum of Arts. The University attendance to include the following eight Classes, each for a Course of six months—Anatomy, Practical Anatomy, Chemistry, Materia Medica, Institutes of Medicine, Surgery, Practice of Medicine, Midwifery, and the following three Classes, each for a Course of three months—Botany, Practical Chemistry, Medical Jurisprudence.

2.—Eighteen months of attendance on the Medical and Surgical Practice of an Hospital containing not fewer than Eighty Beds, along with attendance for six months on Lectures on Clinical Medicine, and for three months on Lectures on Clinical Surgery.

3.—Six months of Compounding and Dispensing of Medicines in the Laboratory of an Hospital, or of a Public Dispensary, or of a licensed General Practitioner, or of a regular Dispensing Druggist.

Exemption to Practitioners.

4.—It will be held equivalent to the Curriculum prescribed in the three Regulations foregoing, to have obtained, upon examination, a Diploma or a License, in Medicine or in Surgery, from a University or other Authority established by law within the United Kingdom, and to have subsequently attended Medical Classes in this University for one year.

Examinations.

5.—The Examination Terms to be two in each year—the *first* to commence on the 20th of April, if a Wednesday, but if not, on the first Wednesday thereafter; the *second* on the 13th of October, if a Wednesday, but if not, on the first Wednesday thereafter.

6. Every Candidate to undergo at least three separate Professional Examinations—the first Pharmaceutical, the second Surgical, the third Medical—to be conducted partly in writing as well as *vivâ voce*, and partly by demonstration.

The *First* to include Chemistry, Botany, Materia Medica, Pharmacy, and the Doctrines of Physics relating to Specific Gravities, to Gases and Vapours, and to Climate.

The *Second* to include Anatomy, Institutes of Medicine, Surgery, and the Doctrines of Chemistry and Physics illustrative of animal Structure and Function.

The *Third* to include the Practice of Medicine, Midwifery, and Medical Jurisprudence.

7.—Every Candidate, not a Master of Arts, must undergo a Preliminary Examination on the Latin Language (the Book to be used being *Celsus de Medicinâ*), and on the Etymology of such Terms in the Medical Sciences as are derived from the Latin and the Greek.

8.—Any Candidate that so desires shall be admitted to each one, or to any two, of his three Professional Examinations, at different Terms; but not to the First Examination, until the beginning of his third year of Medical Classes; nor to the Second, until the end of his third year; nor to the Third, until the end of his fourth year, and until he be twenty-one years of age; nor shall a greater interval than eighteen months be allowed between two successive Professional Examinations, without a full renewal of the previous one or two. The Preliminary Examination must be passed at the same Term as the First Preliminary Examination.

9. In order to be received for Examination, certificates must have been lodged with the Professor of Medicine, on the first day of the month of the Examination Term, shewing that the Candidate is of the required age, that he is of good moral character, and that he has passed through the requisite Course of Professional Education. Along with such Certificates must be lodged a Schedule, filled up in his own handwriting, containing a list of them, and specifying such additional branches of Education, professional and general, as he may have studied.

10.—Medical Degrees to be conferred at the close of each Examination Term.

11.—The degree of Bachelor of Medicine may be conferred on any Candidate who has passed the foregoing Examinations.

12.—The Degree of Doctor of Medicine may be conferred on any Candidate, after passing the foregoing Examinations, if not under twenty-two years of age, or on any Candidate who has been at least six months a Bachelor of Medicine of this University. The Candidate, if a Bachelor, shall state, in a written application, what opportunities of professional improvement he has enjoyed since he was made Bachelor.

STRUCTURE AND FUNCTION OF THE INTESTINAL VILLI.

MM. GRÜNY and Delafond laid before the Académie des Sciences, on the 5th of June, a paper upon the Anatomy and Function of the Intestinal Villi, in which they state, that “the villi of the small intestine are

covered not only with cylindrical epithelium, but also with another form of epithelium, which, from its situation, they have named *capitate*. Each cell of epithelium is provided with a cavity, the orifice of which is sometimes wide open, at others more or less completely closed. At the surface of the epithelium of the villi of the small intestine of a dog, some vibratile cilia not yet described, of which the function is perhaps to displace, when necessary, the coarser chyle, which is in contact with the epithelium.

"Underneath the epithelium, the villus is composed merely of a vascular and fibrous membrane, and within this membrane, of one chyloferous vessel, or canal only.

"In contracting according to their longitudinal axis, the villi become shortened, and take a conical form, of which the base is towards the mucous membrane. In contracting according to their transverse diameter, they become thinner and longer. In fine, they execute movements in every way, as we have before said in our note to the Academy on the 4th of Sept. 1842. In executing these movements, the villi empty themselves of the blood and chyle contained in their vessels, and put themselves in contact with the new parts of the coarser chyle digested from the aliments. Each cell of epithelium must be considered as an organ especially designed to receive the coarser chyle proceeding from digestion, and to convert it into an homogeneous chyle, formed of an infinity of small molecules, held in suspension in a transparent and spontaneously coagulable liquid. These molecules, and the liquid, are the only parts fit to pass through the deep orifice of the epithelium cells, in order to get into the one chyloferous vessel placed in the centre of the villus.

"Each cell of epithelium has a quadruple function:—1st. To fill itself with the coarser chyle proceeding from the digestive process. 2d. To divide and attenuate this chyle, and convert into a pure and homogeneous chyle. 3d. To expel this liquid, so elaborated, and direct it towards the chyloferous canal through the vascular and fibrous tissue. This apparatus we have named chylogenous. 4th. In fine, to imbibe the substances dissolved by digestion, and to make them enter the vascular apparatus."—*L'Experience*, and *Physiological Journal*.

QUALIFICATION FOR GENERAL PRACTICE.

To the Editor of the Medical Gazette.

SIR,

You are, no doubt, aware that the medical institutions in Scotland differ materially in

some respects, from those in England and Ireland. For example; there is no incorporation of Apothecaries in Scotland, nor is there any such distinct class of practitioners; they are either surgeon-apothecaries, or not in any way distinguishable from chemists and druggists; consequently the Edinburgh College of Surgeons include in their examination and curriculum those branches of medical science which are in London, as I understand, left to the examiners at Apothecaries' Hall. Now I and some other readers of the MEDICAL GAZETTE would feel very greatly obliged by your informing us through the medium of your periodical whether the London College of Surgeons includes in their examination materia medica, chemistry, and the practice of medicine, and whether the diploma of the said College is understood to be sufficient to qualify for general practice in all respects, with the exception of compounding and dispensing medicines.

I am, sir,

Your obedient servant,

AN OLD AND CONSTANT READER.

Oct. 21, 1843.

[The examination at the London College of Surgeons includes materia medica and chemistry, only so far as connected with surgery; but does not extend to the practice of physic; neither does their diploma qualify for "general practice."—ED. GAZ.]

PHYSICIAN PRACTISING AS AN APOTHECARY.

To the Editor of the Medical Gazette.

SIR,

I AM at no loss in surmising the source of the communication relating to me, contained in your journal of this day (Oct. 21).

I was recommended to insert in the local paper the letter to which allusion is made, in order to counteract a rumour made current by some "*kind friend*," in reference to my future course of practice; which was calculated to do me much injury.

Not feeling myself called upon, however, to give your *disinterested* informant the explanation he probably desires, I beg to state I am most fully prepared (should it be required), to satisfy the College of Physicians that my intentions of practising are perfectly consistent with their regulations. I shall feel obliged by your inserting this in your next number.—I am, sir,

Your obedient servant,

FRED. GEO. REED.

Hertford, Oct. 23, 1843.

NOTTINGHAM LUNATIC ASYLUM.

On the 28th of September Dr. John Calthrop Williams, one of the physicians to the Nottingham General Hospital, was elected physician to the Nottingham Lunatic Asylum.

UNHEALTHINESS OF PARTS OF THE METROPOLIS.

THE neighbourhood of Temple-Bar and its western courts, or alleys, are at present an unhappy illustration of the fact, that closely-built houses, densely populated by the indigent or poorer classes, are dreadful sources of disease and contagion. This unhealthy spot, during the last twelve months, has forcibly attracted the attention of the parochial surgeon, whose duty it has been to attend patients in their abodes of filth, destitution, and disease. Many of the houses are here let out in separate apartments to as many families, where they cook, wash, and sleep in a confined space scarcely to be credited, without any control, their landlords living away from the premises. Consequently, from an accumulation of filth and concomitant causes, fevers are very prevalent. Last week, a family suffering with typhus were removed to the Fever Hospital, where the husband and wife died, but were brought back in shells to their former domicile, when they were deposited in the attics, and there still remain. In another house, in Ship Yard, an unhappy woman expired last Friday in a fit, and remains at present without the last offices of humanity having been performed. In short, similar cases are, unhappily, of frequent occurrence.—*Times*.

CLINICAL REMARKS
UPON CASES TREATED IN THE ST.
MARYLEBONE INFIRMARY.

By B. PHILLIPS, F.R.S.

THE series of clinical observations which are to follow have arisen out of cases treated in the Saint Marylebone Infirmary. I have refrained from detailing the cases at full length, because the particular relation of them is often tiresome, and the reading, for the most part, irksome. I have therefore preferred to refer more particularly to points presenting a practical interest to the student: the details he had opportunities of acquiring himself. The subjects I propose to include in these observations are, *injuries of the head, secondary syphilis, diseases of the urethra and the rectum; bubo; scrotal hernia of large size, and hip-joint disease.*

Although much caprice is shewn in the admission of accidents into the Infirmary, a considerable number of serious injuries are treated there in the course of a year. Of secondary syphilis in its most aggravated form, many specimens are annually seen. Among our aged poor, stricture of the urethra, and diseases of the prostate, are frequent; so are irreducible scrotal hernia of a large size, and diseases of the rectum. Our schools also furnish us with many examples of hip disease. Those are the materials which called for the remarks which will follow; and although much that may be said may already be well known, something of practical value may find its way where it did not exist before.

Injury of the Head.

A. B.—, æt. 53, a chimney-sweep, was picked up in the street by a policeman: he was almost if not quite insensible, and his appearance shewed that a violent contusion had been sustained by the nose, but whether from a fall or from any other cause did not appear. On admission he was still insensible; but

upon a careful examination it did not appear that there was any fracture of the skull. Gradually he recovered consciousness, but it then became evident that his mental faculties were very weak. Whether they had been so before the accident we had no means of ascertaining. He recovered sufficiently to express his wants, and to take food with great relish; he lived 25 days after admission. One day, while eating his dinner, his head hung upon his breast, he soon became comatose, and in a few hours died. The examination after death revealed a fracture of each orbital plate; a small portion was detached and driven inwards on each side. There was no effusion of blood; there was a little purulent matter at the injured points, and the dura mater was slightly inflamed. In this case the orbital plates had been broken by a blow received upon the nose; the nasal bones having resisted fracture, the force was directed through them upon the orbital plates, which gave way.

You also recollect the case of a lad of 15, who fell from a scaffolding, and severely injured the left frontal region. When admitted he was insensible, the scalp was torn off for a space of two inches, but there was no fracture, although there was a slight indentation. The symptoms, as in many cases, were mixed, partly those of concussion, partly compression. As he recovered from the effects of the concussion, it was observed that the right leg was powerless. So it continued, accompanied by occasional headache, sometimes intense, for upwards of a fortnight; when it was discovered that the loss of power was dependent upon injury to the part, unattended with much contusion.

In March, 1840, an Irishman, æt. 27, a plumber's labourer, living in Cato Street, was murderously assaulted by some of his own countrymen, and left in a state of insensibility. From this he recovered during the night, and on the following morning he got his wounds dressed, and proceeded about his usual daily labour. Although he continued

to work, he felt a certain uneasiness, not amounting to pain, in his head. On the twelfth day after the attack he took a glass of gin; after that he became giddy, and on his way home he fell against a shop window: received no material injury, but thought it necessary to apply for medical advice. He was seen by two medical men, but no idea of fractured skull was presented to their minds. He had purgative medicines administered to him, as well as mercurials; but his health declined. On the day before his death, the 23d from the receipt of the injury, I was requested to see him. I found him heavy and stupid, but quite capable of answering the questions put to him; the pupils were large, and rather sluggish, the tongue was dry, brown, and coated; the respiration tolerably easy: when requested to do so, he raised, without apparent difficulty, each arm and leg. Upon examining the head, I found a wound of nearly five inches long, extending obliquely backwards through the left parietal region; it was suppurating, and full of granulations. I ascer-

tained that it had been examined twice in the 24 hours subsequent to the injury, but that no fracture had been detected. The man died on the following day. An examination of the head was made after death: on removing the scalp a certain quantity of fetid pus escaped through a cut three inches long, extending fairly through the external table, and corresponding to that in the scalp; it was a fair cut through the bone without depression, and had been inflicted, probably by the edge of a flat iron or shovel, which were among the weapons used in the assault. On removing the skull-cap, the dura mater on the injured side was found greatly shrivelled; and much of that hemisphere of the brain was broken down into a purulent pulaceous mass; the quantity of that matter which escaped was above six ounces. Implicated in the dura mater at the point corresponding to the injury of the external table, and detached from the skull-cap, was a piece of the inner table of the accompanying dimensions.

June 3d, 1841.—Sarah Shears, a married woman, æt. 33, was admitted into the Marylebone Infirmary, labouring under the effects of severe concussion of the brain. The history of the injury is tragical enough: her husband, who was a green-grocer, was unfortunate in business, and in consequence became a denizen of Whitecross Street Prison for six months. While he was undergoing this incarceration, his wife formed a criminal intimacy with another man. Soon after the husband was discharged from prison he was told that this connection still existed, and much quarreling was the result. One day he ascertained that she was to meet her paramour; he took means to satisfy himself that the information was correct, he awaited her return home, and with a poker or shovel he struck her twice or three times over the head; she fell down, as he believed, dead; he then destroyed himself by cutting his throat. The patient on her admission was insensible, the surface of the body cold, the pulse small and unfrequent, respiration very slow. Warm applications were made to the surface of the body, and warm fluids were introduced into the stomach. She soon recovered consciousness, but remained for the succeeding two days in a somewhat comatose condition. On the scalp were three wounds, two comparatively unimportant; the third, which extended obliquely backwards along the parietal

region, was about three inches long: at that point the skull was exposed, and a deep gutter extending for three inches, and implicating the whole thickness of the external table, was discovered. A probe made it pretty evident that the inner table had given way, although there were some suspicious symptoms of cerebral inflammation, there were none which seemed to justify any further exploring operation; but mercury was guardedly administered so as to excite the usual action, the diet was rigid, and the bowels kept free. The case did well, and she was discharged July 8th.

In this class of cases, where there is fracture of the skull with depression, a question which passes through the surgeon's mind very frequently is this—should I trepan? Generally the question is resolved in the negative; it is an operation not frequently performed. I am satisfied that the reasons which lead to such a conclusion, in similar cases, are very dissimilar. One man objects to the operation under any circumstances; another, though aware there is a depression with a wound of the scalp, will wait till urgent symptoms are developed, and then he will trepan; another, even in the face of threatening symptoms, admitting that there is a depression, will wait because there is no scalp wound; another will operate whether there be a scalp wound or not, provided there be a depressed bone, though there

may be no urgent symptoms; upon the assumption that the necessity will arise, and that it is better to operate before inflammation has set in.

I entirely agree with Sir Philip Crampton, that it is very desirable that a greater uniformity should exist in the practice of surgery in the different countries of Europe than at present obtains; but I would go further, and say, that it is first desirable that more uniformity should exist in the practice of the same country or even of the same town. It is surely not necessary in the present day to lay down the proposition that in a given class of cases one mode of treatment may succeed in a larger number of cases than another. At the present moment it is matter of the greatest diversity of opinion, whether, in certain injuries and diseases of the foot, where amputation becomes necessary, a point just above the ankle or just below the knee should be the place of election. One man recommends that the hernial sac should not be opened when an operation is performed for the relief of strangulated intestine; others that it should. Some advise that when pus or other fluid occupies the cavity of the pleura, a puncture should be made in front, others behind. Some recommend that the opening should be made with a trocar, others with a bistoury; in the obliteration of varicose veins, the practice of one hospital is to use caustic potash, of another to place a needle under them. It is, however, needless to multiply examples to prove what is already so well known.

That absolute uniformity of practice is desirable in a progressive science I do not maintain, because perfection may be unattainable, but greater uniformity than at present obtains could not fail to be useful. Though I admit all this, and though I agree in the opinion that the publication of clinical lectures is one means for attaining the end, still every one will concede that a fair report of all the cases in an hospital is the only mode by which the end can be fully answered. If we had only clinical lectures and clinical remarks to depend on, they would afford us only a sorry means of accomplishing what seems so desirable; and during the last seven years there has been a very decided falling off in this respect, both in the number and importance of such communications.

With respect to our subject of consideration—the operation of the trepan—Sir Philip Crampton, in 1832, says, “that the modes of practice in certain severe injuries of the head are different in London and in Dublin: that the difference consists in this—that in fracture of the skull, with depression of the bone, the trepan is less frequently employed in Dublin than in London.” I am not sure he was right at that time; sure I

am that at the present moment as much indisposition is felt to use the trepan in London as there can be in Dublin. It is true that if in the one case we take Mr. Pott to represent the existing doctrine on the subject in London, and Mr. Dease in Dublin, the discrepancy is very great; but the ideas on this side of the water have undergone a great change since the time of Mr. Pott, and I very much doubt whether Sir Philip Crampton would not think it proper to use the trephine in cases where Mr. Dease would have declined it. Still, in practice, the rule laid down by Mr. Dease, that “in fractures of the skull with depressed bone, whether complicated with wound of the scalp or otherwise, no attempt should be made to raise the depressed bone, unless very decided symptoms be present of compressed or irritated brain,” may be more strictly followed in Dublin than in London. Here, if we take Sir A. Cooper and Sir B. Brodie as guides, we must come near to the conclusion, “that if the depressed bone be exposed, the trephine must be applied to elevate the depressed bone, whether symptoms of injury of the brain exist or not.” Now here is a tangible point which might have been decided had a careful report of cases been preserved, and a healthy rule of practice might have been adopted. It would have taken shape in this way: a hundred cases of fractured skull with depression, but without symptoms of injury of the brain, were left to themselves; seventy recovered; a hundred as nearly as may be similar cases were in each case subjected to the operation of the trephine; sixty recovered. In this way we might come to the conclusion, that in all cases of fractured skull with depression, but without symptoms of injured brain, the trephine should be avoided. This is a question which might be decided in the London hospitals in the next ten years, if a judicious and uniform system of enumeration were adopted.

Any one who takes the trouble to look through the pages of periodical literature will find a very large number of cases of fractured skull, with depressed bone, which got well without the use of the trephine; very many even in which there were symptoms of injury of the brain; very many in which the trephine was applied in the absence of symptoms of injured brain, and in which death seemed to be the result of the operation. At one time I had proposed to collect the materials from those sources for a decision on the question, but the descriptions were often so vague that I abandoned the task in despair.

We must now look a little more narrowly than is generally done to the opinions of the great advocate of the trepan in England, and ascertain whether they have been fairly represented. Mr. Pott, who was a man of

original thought and great surgical ability, laid down as a rule for the guidance of his followers, that "as the number of cases of fractured skull brought under his observation were so many, he had been enabled to satisfy himself that although now and then he had seen some few of them do well without the use of the trephine, yet the much greater number whom he had seen, who had not been perforated, perished with collections of matter within the cranium, and for such, my belief that there is no other relief in art or nature, has, I must acknowledge, rendered me so very cautious and diffident, that although I will not say that I would always, and invariably, perform the operation, in every case of simple fracture, yet the case must be particularly circumstanced, the prospect much fairer than it most frequently is, and my prognostic delivered in the most guarded apprehensive manner, when I omit it." In another place he says, "perforation is absolutely necessary in seven cases out of ten of simple undepressed fractures of the skull. Still, Mr. Pott admitted "that in matters of this sort positive proof and conviction are not in our power; all that we can do is, by making a comparison of the conduct and event of a number of similar cases, to come as near to truth as we can, and to get probability on our side.

The cases recorded by Pott, in which he used the trephine, amount to 27. In nine of these, the operation was performed to prevent the development of those symptoms which accompany or follow severe contusions of the cranium. In ten, to prevent the mischief likely to follow in cases of fracture without depression. In one, to remove a portion of depressed inner table. In five cases, to relieve the brain in fractures with depression. In three, to relieve the brain from extravasated blood. Of the first nine cases, there was only simple contusion in three; wound of the scalp, with contused cranium, in six. In five, there was loss of consciousness; in four, there were no pressing symptoms. In eight cases, pus followed the trepan; in one, it was blood. In six cases, the fluid was between the dura mater and the bone; in three, it was under the membranes. There were five cures and four deaths. Of the ten cases of fracture without depression, five had simple contusion of the scalp; five had contused wounds. Pus followed the trepan in six cases, blood in two; in the remaining two there was no collection of fluid at the point. There were six cures and four deaths. In the five cases of fracture with depression there was more or less severe contusion of the scalp; in three, there were wounds. There were two cures, and three deaths. Of the three cases of extravasation, two existed without appearance of external violence; in one, there was

a wound. Two were cured, and one died. Of these 27 cases, the trephine was applied in twenty-two instances after the fourth day; in seven of these cases it was used twice; in three, three times. Of those twenty-two cases, eleven did well. Of the remaining five cases the trephine was used on the first day, and three did well. It is only right to say, that in one of the twenty-two cases, in which death occurred, the patient was doing well, when he was attacked with peripneumony, of which he died. Now, although Mr. Pott would seem to recommend the immediate use of the trephine in cases of simple fracture without depression, yet of the 27 cases he has left on record it was so employed only in five instances. If we, then, judge from his practice, we should conclude that he carefully watched his patients, and did not interfere by operation until the symptoms imperiously required it.

Mr. Abernethy, an able successor in the same hospital, saw so much mischief from the almost indiscriminate use of the trephine, that he ultimately regarded it with less favour than was justly due to it, and urged so many and such valid reasons against its general employment, that a very large number of the medical men on this side of the channel have seen, or fancied, so much evil to attend upon the operation, that they have been content to let the trephine get rusty in its case. Mr. Abernethy's ideas with respect to the operation were summed up in these words:—"From all, therefore, that I have learned from books, as well as from the observations I have made in practice, and from reasoning upon the subject, I am disposed to join in opinion with those surgeons who are against trephining in slight depressions of the skull, or small extravasations on the dura mater."

Mr. Guthrie, whose experience on the subject is very great, says: "The propriety of dividing the scalp in order to examine the bone beneath, which is evidently depressed, and thus rendering a simple, although comminuted fracture, a compound one, is a matter of much greater importance, the decision of which rests upon the still more essential point, viz., whether a depressed portion of bone ought, or ought not, to be removed. "I place no reliance on the supposition that there is more real danger in a case of fracture with depression in which the scalp has been divided, than when it has been only bruised, and not divided; and I apprehend that in all cases in which a fracture with marked depression is known to have occurred in an adult, it is the best practice to divide the scalp, and ascertain the nature and extent of the depression. If the result of a great number of comparative trials should prove in favour of never, under any circumstances, raising a depressed por-

tion of bone in an adult, but of leaving it to the efforts of nature, an incision, in order to ascertain the state of parts, ought not to be made; but as such result is not likely to be obtained, according to my observations and experience, the practice recommended appears to be the best."

Sir B. Brodie, than whom no one is capable of giving a sounder opinion, lays down as a proposition, favoured by the evidence already adduced, that "it is more prudent to abstain from the use of the trephine where there is a fracture with depression of the cranium, producing at the time no unfavourable symptoms." Still, he ultimately agrees with Sir A. Cooper, that where the fracture and depression are complicated with a wound of the scalp, we should not hesitate to apply the trephine. Although he does not detail the numerous cases which have come under his observation, he says that among them were of course many of fracture with depression, followed by suppuration between the dura mater and the bone. On referring to them, he says, "I find that the cases in which suppuration takes place, where the scalp is entire, have been comparatively rare." Mr. Pott's experience is exactly opposed to this in almost every case where there was only confusion with or without fracture: if sufficient time elapsed before the operation for its formation, pus was found there. This difference shows the necessity for observing on a very large scale, before rules of practice are deduced. Sir B. Brodie does not give the results of a small experience, nor does he make his statement from a general recollection, "but on the authority of written notes made at the bedside of the patients, and, for the most part, before the question which they illustrate had ever presented itself to my mind." "Taking all these facts into consideration, and endeavouring to give its proper value to what may be urged on either side of the question, I cannot but acknowledge, whatever may have been my first impression on the subject, that it appears to me at this moment that the views of Sir Astley Cooper are well founded; and that in those cases where depression exists without any symptoms, or with only trifling symptoms arising from it, the surgeon can follow no better general rule than this: if the depression be exposed in consequence of a wound of the scalp, let him apply the trephine and elevate the depression; but if there is a depression without a wound of the scalp, in consequence of the accident, let him not make such a wound by an operation. An exception may, perhaps, be properly made with respect to very extensive depressions of the cranium, which it may be prudent to expose and elevate at all events, not because there is a greater danger of suppuration from these than from smaller

injuries, but on account of the ultimate ill consequences which the patient may experience if the brain be left permanently subjected to a very considerable pressure."

Those are the opinions which at present prevail on this side the channel. Now for the other. No man had better means of judging on the proper course to follow in such cases than O'Halloran. He says, p. 2, "The various disorders incident to injuries of the head have been by no means discriminated with sufficient precision, nor have their symptoms or modes of treatment been clearly ascertained. Even the use of the trephine is now more indefinite than it was a century ago. Without doubt, there is no part of the habitable globe that for half a century past has afforded such an ample field for observation on injuries of the head as Ireland in general; this province of Munster in particular. I have had no less than four fractured skulls to trepan on a May morning, and frequently one or two. In the course of above 35 years' practice, I may safely affirm, because truly, that on an average, one month with another, from three to four cases have fallen to my share of either fractures, concussions of the brain, or extravasations. To a certainty, the observations of writers for more than a century past, far from elucidating the subject of injuries confined to the skull, and their effects, have visibly tended to throw it into greater confusion than it had been in; for instead of determining with precision the cases in which an operation (in itself extremely painful and cruel, and in its consequences dangerous) shall *only* be had recourse to, they have so multiplied them that scarce a hurt on this part, attended with untoward symptoms, that does not verge to trepanation. A fracture ought only to be sought for where the injury is received. No danger can arise from delaying this inquiry for two or three days; for it is by no means a consequence that because the skull is fractured trepanation must follow; for a fracture of the skull merely as such will heal as safely as that of the leg or the arm. It is where the bone is depressed on the brain, it is where we apprehend that the depressed parts may form acute angles, which in course of many days may cut through the membranes and wound the brain itself, that the operation becomes necessary. In fractured heads, when, upon removing the integuments, a simple division of the bone only appears, and the depression at its edges but slight, when, by a depression of the finger here, no excessive pain or heaviness appears, there is every reason to expect that we have little else to do but to dress the wound lightly with soft lint, nor suffer it to make much progress in healing for twelve or fifteen days, when, if no heaviness, drowsiness, or stupor

appear, we may conclude all is safe within, and then treat it as a common wound. But when there is any considerable depression of the bone, or the fracture is at all extended, the sooner the operation is performed the better. For though, in the first instance, we may safely delay the operation, yet I think it much more safe and prudent, in fractures of the second class, not to wait for symptoms of depression."

Page 209.—"Every fracture with depression necessarily demands the trepan; and although cases of recovery without it may be adduced, the surgeon is inexcusable who fails to attempt, at least to propose and press it. Simple fracture with depression, when relieved on the spot, or in the space of two or three days, almost always terminates happily. In the course of more than 200 cases of this simple kind, I cannot recollect a failure in a single instance. Let us, for example, suppose an extended fracture on the side of one of the parietal bones, with a severe depression without a wound of the integuments. The touch will, to a certainty, direct you to the point of the bone deepest immersed. The head being close shaven, place the crown you would wish to use over the sound bone to the edge of the depression; with a pen, mark its periphery; then, with your knife, make a circular sweep to the bone, and remove integuments and pericranium; proceed to operation. Introduce through the perforation your elevator, and raise the depressed parts, &c.

"There is no immediate existing symptom by which a fractured skull may be known—our information must be derived from the touch and the probe. A fracture with depression is generally followed with marked symptoms; in some these appear sooner, in others later, but in none exactly the same. They are sometimes a darting pain from the sore to the forehead and eyes, an incipient heaviness, torpidity, and weight in the head. The slightest noise disturbs them. They grow lethargic, often convulsed, and, if not speedily relieved, the scene closes with death. When called in to a patient with any or all of these symptoms, especially with a heaviness of the head, and lethargic tendency some days after a violent injury to the head, you may conclude them the signs of a depressed bone. As these symptoms form the exact criterion between a simple fracture of the skull without, and a fracture with, depression, and that the former demands no operation, whereas in this latter case it cannot be dispensed with, we shall go to elucidate the position by facts. Although many instances can be given where nature unassisted has relieved herself in very desperate cases, they ought not to give too much confidence to the young surgeon, and to induce him to trifle with the precious time before

him in such cases: whilst I suggest every incentive to exert our abilities to relieve nature, however unpromising the appearance, yet I constantly recommend, in every depressed fracture, when called upon in any reasonable time, never to lose a moment, nor wait for the dangerous symptoms of depressed bone appearing.

While in Scotland, Mr. Syme says, "It was formerly thought that the symptoms of compression perceptibly required the immediate performance of an operation for raising the depressed portion of the skull, or affording vent to effused blood. The ample experience of a different practice, followed in modern surgery, has proved that in most cases, unless the substance of the brain has suffered serious injury from concussion, the condition of the patient labouring under concussion will not be altered for the worse, and, in many, will amend, if some days are allowed to elapse after the injury has been sustained before proceeding to trepan the skull. If the symptoms do not diminish, or if they increase, the operation must be performed. Should depression of the skull be associated with a wound of the scalp, penetrating to the bone, a very short trial of the means calculated to supersede the necessity of an operation will be sufficient, as the fracture will be a compound one, and consequently not unlike to be aggravated in this important respect by trepanning. On other occasions, two or three days may generally be allowed to pass without any bad consequences."

Here, then, in a few words, is the difference. O'Halloran, in every depressed fracture, would take means to elevate the bone at once. Dease would make no attempt unless very decided symptoms of compressed or irritated brain were present. Sir B. Brodie believes it is more prudent to abstain from the use of the trephine where there is a fracture with depression of the cranium, producing, at the time, no unfavourable symptoms; but he agrees with Sir A. Cooper, that where the fracture and depression are complicated with a wound of the scalp, we should not hesitate to apply the trephine; while Mr. Syme would wait, even in a case of compound fracture with depressed bone.

Let us now see whether, in other countries, there be equal discrepancy on this point.

Desault, in the last five years of his practice at the Hôtel Dieu, only used the trepan once. He and his follower, Bichat, comfortably settled that, in the great majority of cases, we cannot detect the fracture or the extravasation, and that, if even we could, the patient would get well without operation. No doubt the symptoms are often very uncertain, but not so much so as they seek to

prove, and generally we do not, as they allege, confound the symptoms of compression with those of inflammation. If Bichat could not discriminate between them, he was right to abstain from the operation. The abuse of the trepan by others, he met by a counter-abuse. As against Quesnay, they may have had right on their side, but then Petit had lived before them, and the reproach of indiscreetly using the trepan cannot be fastened on him, though it may on Quesnay.

In Germany, the representatives of the two systems are Richter and Schmucker—the former approaches near to Pott; the latter to Dease. The first volume of Schmucker contains fifty cases of wounds of the head. At the siege of Schweidnitz he established an hospital for injuries of the head alone, and there it was that those observations were made. In the first twelve cases the wounds were trifling, or if the bone was bare there was very little injury done to it; the patients not being incapacitated from pursuing their ordinary avocations from the first. After some days, symptoms of cerebral disturbance were manifested; the trephine was applied, very little internal injury was detected. Little as it was expected, the patients died, and pus was found between the pia mater and arachnoid, but the brain was free from disease. Such results, from apparently such slight causes, produced in Schmucker's mind a doubt of the propriety of his mode of treatment, and he resorted to the use of cold water.

Klein, in his *Journal of Surgery*, lays down a broad rule, that the trephine should always be applied when the bones are fractured, though there may be no sign of cerebral irritation. He believed it should be done as early as possible, and that the fatal consequences which may follow in the case, where the operation should be deferred, should fall on the surgeon. Chelius' rule is, "that in all cases of fracture, with or without depression, and in penetrating fissures, in incised wounds with a blunt sabre, which penetrates the external table and the diploe as far as the inner table or the cranial cavity, in wounds made with a sharp sabre, when the dura mater is also wounded, in penetrating wounds made by pointed instruments, in gun-shot wounds which affect the bones of the cranium and the diploe, in cases of disjointed sutures, the trephine should be used." But probably the warmest partisan of the trephine, in the present day, is Schindler: he says, "I place as a principle, founded upon the experience of many hundred observations, that whatever may be the form of the injury done to the bones of the cranium, whatever be the instrument by which it has been made, we ought at once to lay bare the part to ascertain the nature of

the lesion; we must not for a moment consider the pain of the division of the soft scalp parts, for we should know that in the greatest number of cases the salvation of the patient consists in the opportune employment of the trephine." The only cases in which he admits that we may be justified in deferring the operation are, those in which the edges of the fractured bone are so far separated as to admit of the free escape of fluid, and a probe for the purpose of ascertaining whether there be any spiculae—cases of fracture, with or without depression in infants—cases of slight depression admitting of the free escape of fluids—cases of wounds by a cutting instrument not penetrating into the cranial cavity—cases in which a gun-shot wound has not caused the separation of the pericranium. He admits the operation to be useless, when the portions of bone can be removed without the trephine—when the injury is so great that all is powerless—in fractures extending to the base of the skull.

Graefe, in his *Journal of Surgery*, 9th vol. says, that the trephine makes a wound grave in itself, and likely to increase the already existing traumatic irritation. Schneider mentions nine cases of wounds of the head cured without the trephine: the patients had fallen from a great height. Kern, in his *Treatise on Wounds of the Head*, and on the Trephine, 1829, strongly argues against the use of the trephine; he only admits the propriety of employing it in cases of large extravasations of blood, when easily detected. Rather than risk one or two useless perforations, he would trust to the power of absorption. He rejects it in caries, but thinks it justified in severe cases of fracture with depression, though in most cases the patients will die. He is satisfied that of twenty persons subjected to the operation, in nineteen it is uselessly employed.

With regard to the use of the trephine, then, opinions are very various. One party, numbering in its ranks Dease, Abernethy, Desault, Walther, and others, seek to restrain its employment within very narrow limits; they would apply it only when consecutive accidents are manifested with a certain intensity; while another party, including Pott, Sabatier, Zang, Schindler, would advise its application more generally; they would use it not only after the development of cerebral mischief, but in order to prevent them. The one fairly rest their opinion on the facts, that fractured skulls, with or without depression, are frequently cured by judicious treatment; that extravasated blood may be absorbed; that the operation of the trepan is dangerous; that we add to an exciting injury another which is often fatal. The other party say, that the inner table is brittle, and that spiculae may irritate the brain or its membranes; that the

vessels which unite the dura mater with the cranium are frequently destroyed and cause hæmorrhage; that the diploe is very commonly injured; that suppuration may be set up, and that the signs of compression and irritation may be consecutively developed; that when those symptoms are manifested we cannot expect much even from the trepan; that even when blood is extravasated, if we wish for its absorption, we may wait until cerebral inflammation is set up. No one, however, can deny, that fractures, with or without depression, may get well without the trepan. We might even admit, that of ten cases operated on by the advocates of the trepan, two may have got well without it. Still it must be equally admitted, that when it is not resorted to until serious symptoms set in, we have no right to argue against the operation in the abstract. What danger may immediately belong to the operation itself it is not easy to say. Mr. Guthrie thinks one in ten would die from it; other experienced surgeons think differently.

The two latter cases I have mentioned show the difficulty of laying down general principles to meet all cases of fractured skull. It has been laid down as a rule, that where you have incisions fairly through the outer table and diploe, without depression, that it is almost certain the inner table, which will not bear cutting, has been fractured, and driven in upon the brain. That after examination with a blunt probe, if it should be found to be the case, the use of the trephine is indicated, even in the absence of symptoms. A similar rule was laid down by Delpech: he says, all fragments of the inner table pushed in towards the brain ought to be removed. Now, if we look at the above cases, we might be disposed to admit that if means had been used to remove the piece of bone in the first case, the man might have been alive at this moment; but if we apply the same reasoning to the other case, do we not see that we should have exposed the life of the woman to much greater peril than that which at the moment stared her in the face? It may be said that a probe passed through the incision in the external table would inform the surgeon whether or not there were any displacement of the inner table, and that we should then be prepared to act with proper data. In the closet such reasoning might appear to be admissible, but the practical surgeon knows that such things are not so easily ascertained. Supposing the interval between the two tables to be considerable, how is the surgeon to feel secure that it was not the normal condition in the particular case? and would he be justified in applying the trephine because he found a greater than usual space between the two tables. Besides, even if there were a fracture of the

inner table, with depression, is it sure that the probe would detect it? Let us go a step further: supposing we had ascertained that the inner table was fractured and depressed, should we be warranted, in the absence of any pressing symptom, in applying the trephine? Is it certain that a depressed bone, which has for some hours occasioned no symptom of compression, may not continue for some years equally innocuous? Is it certain, that when the symptoms of compression are wanting, the operation of the trepan may not be more pregnant with danger to the patient, than allowing things to remain in *status quo*. Take the case of the Irishman: would a man have been justified, the morning after the accident, in stopping him on his way to his work, taking him to an hospital, and proceeding to remove the detached bone; or, would he have been justified in the second case, where the symptoms of concussion are more severe and continued for a longer time, and after having discovered the incision through the outer table, but failing to obtain any other indication than presumption that the inner table had given way—would he, I say, have been warranted in applying the trephine?

CONTRIBUTIONS TO ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

The Cervical Ribs in Man: a Memoir.

A VARIETY in the number of the ribs in man attracted very early the attention of anatomists. M. Hainauld, in 1740, submitted to the French Academy of Sciences some researches on this point: his memoir, entitled, "*Recherches sur les causes de la structure singulière qu'on rencontre quelquefois dans différentes parties du corps humain*," is a remarkably philosophic production for the period. In that memoir he describes and gives drawings of three anatomical preparations, which he speaks of as being in his possession. I shall first allude to these three preparations, as being each remarkable either in itself, or for M. Hainauld's remarks regarding it: this will lead me naturally to those inquiries I have myself made during the last quarter of a century into the same subject, and which for seventeen years at least I have annually detailed at con-

siderable length in my anatomical lectures; and, finally, I shall make a few remarks as to how far, and how fully, the laws of transcendental anatomy explain the varieties in question.

The vertebræ which, in man, carry distinct ribs are twelve in number; they are called dorsal, and their distinguishing character is chiefly, but not solely, that they carry ribs. They have other distinct characters, no doubt, but this is the chief one; it gives rise to the presence of facets, or articular surfaces, on these vertebræ, which are wanting on the others, for this very reason, no doubt, that in man these other vertebræ do not carry ribs, and were never intended to do so. These vertebræ, perhaps, might have been more appropriately called *costal* and thoracic, as carrying ribs; but this name is also open to objections. The vertebræ superior to these twelve dorsal are always called cervical; whilst vertebræ of three regions, if not four, follow them; these, of course, are the lumbar, sacral, and coccygeal. Similar arrangements hold in all mammals, with one exception, to be afterwards considered; but in mammals merely, for it was soon discovered that in other animals distinct ribs were carried on other vertebræ than the dorsal. In birds these are obvious on certain of the cervical vertebræ, and rather than change the name of the vertebræ, anatomists preferred changing that of the ribs; so they called these ribs on the cervical vertebræ, cervical ribs. Other animals lower in the scale were found to carry ribs on other vertebræ, as on the lumbar. In man himself it was found that occasionally a rib might be found on one of the vertebræ (but only on one) called cervical. And finally, the doctrines of transcendental anatomy prevailed, assigning to all the vertebræ of the human embryo the elements of ribs—rudimentary ribs, if I may so say, which, according to circumstances, may or may not be developed. This latter assertion is, of course, a mere theory, unsupported by direct or intuitive inspection, resting, however, on strong analogies, and supported by the history of the human embryo, and by the great doctrine of unity of formation.

Throughout this memoir the object is to inquire into, and if possible explain, varieties and exceptions to the

"laws of species." The law of species (individuality) gives to man twenty-four ribs, that is, twelve on either side: the transcendental law, or of unity and general formations, adds two more; I mean free and distinct ribs, for in regard to others which are now found running into the adjoining processes, as the sacral, there cannot, I think, be much doubt in regard to them. But here let me first state, that M. Meckel's theory that *the ribs* (thoracic) are merely the prolonged anterior roots of the transverse processes of the dorsal vertebræ, is contradicted by the plainest facts.

What, then, are the leading points to which I beg leave to direct the reader's attention? They are, first, the occasional presence of cervical ribs in man; secondly, their presence in mammals; thirdly, the application of the laws of transcendentalism as applied to explain these varieties.

It is a singular circumstance that M. Hainault, with whom probably originated these inquiries, did himself observe nearly all the more striking forms which the cervical rib may assume in man; and he had the good fortune to stumble on one form which, so far as I know, has never again been observed since his time. Here are his observations in his own words:—

"I have the skeleton of an adult, in which the first rib on each side, well-formed posteriorly, and articulated with the first dorsal vertebra, unites itself with, and becomes confounded with, the second rib, which, by this union, becomes larger than it usually is."

FIG. 1.

"In looking at this skeleton in profile, or in front, twenty-two ribs only are seen. Morgagni, Fantonius, in his Commentary on the Epitome of Vesalius, speaks of the confusion, or uniting, of the ribs similar to the above.

"I have the skeleton of a fœtus about seven months *in utero*. On the left side, the five superior ribs are united posteriorly to each other, but are separated or distinct anteriorly. The sixth and seventh are also somewhat united to each other. These, then, are examples of a seeming deficiency of ribs: and besides, it is not surprising that one or more ribs may not be developed.

Now, admitting freely the possible, even probable correctness of M. Hainauld's explanation of the specimen from which fig. 1 was taken, (see *Mem. de l'Acad. des Sc.* 1740), a very different view might be taken of this matter. The following figure, drawn from a specimen now before me, will require first to be attentively considered by the reader.

FIG. 2.

explain more fully afterwards. The descriptive anatomist, when he speaks of it as being placed there for the attachment of the scalenus, merely shows that he is wholly unacquainted with its nature.

It must be admitted, however, that I know nothing of the history of the preparation, and so far, therefore, is my explanation open to objections: but not so the real nature of the process on the inner margin of the rib, whose history I shall fully explain before the close of the memoir.

Before proceeding to M. Hainauld's next observation, I may as well give figures of the preparations in my possession analogous to the two already described.

FIG. 3.

This is a fore-shortened view of fig. 2: it tends to confirm my explanation of the preparation.

FIG. 4.

The extraordinary size of the process on the inner margin of the first rib is, in this preparation, quite remarkable. Nothing is known of the history of the specimen, but, from its appearance, I feel disposed to conjecture that the tendon of the scalenus may have been ossified, and that therefore the preparation does not illustrate the history of the process in question.

Hainauld's figure is coarsely and very imperfectly drawn, so that it is impossible to decide positively regarding it; but I feel disposed to consider it as analogous to the one I have given. Now the rib which he considers to have been the first, or true rib, I believe to have been merely the cervical rib carried occasionally on the last cervical vertebra. His assertion that it was carried on the first dorsal vertebra cannot altogether be depended on, as I shall afterwards show; whilst the reader will be pleased to observe the process on the inner margin of the first true sternal rib, to which the anterior scalenus muscle is attached, and which seems to be formed, when present (for it is far from being always so) by the ossification and union of the cartilaginous termination of the cervical rib: this curious fact I shall endeavour to

FIG. 5.

Although the preparation from which this figure was taken was dissected, as it were, before me, I failed in obtaining the requisite details: I give them, therefore, in a note, as incomplete, and not quite worthy of being altogether depended on: its history, however, may happily be illustrated by some future observer*.

I return now to M. Hainauld's next observation; he had the merit of discovering the nucleus of bone anterior to the transverse process of the 7th cervical vertebra, so frequently present, so varied in its form, and which is, in fact, a rudimentary cervical rib under whatever shape it appears. This beautiful observation, superficial readers are apt to ascribe to Beclard.

"But it is not so easy to understand how a small number of persons may have one or two ribs more than the rest of men. If it be said that nature has given to some embryos the germ of one or two ribs, which she has refused to all the others, one would be entitled to look on almost all singular and monstrous productions as having been so from the beginning (which it would be difficult to be persuaded of). On the other hand, it is not easy to imagine that two children being enclosed within the same womb, one of them shall have been entirely obliterated excepting two ribs merely, left to his brother, and which have placed themselves precisely on the two sides of a vertebra."

"Now here is the mode in which, in

my opinion, these supernumerary ribs are formed. I have found, in many subjects, that the ossification of the transverse process of the seventh cervical vertebra happens in a different way from that of the other cervical vertebrae."

"In the young person, the osseous mass which forms the processes of the cervical vertebrae is united to the lateral parts of the same vertebrae by a cartilage which disappears with age. A portion of this mass divides into two sorts of arches, one anterior (Fig. 6, B), the

FIG. 6.

FIG. 7.

other posterior (C), which, as they grow, proceed to meet each other, forming, by their union, the transverse process, and the foramen or hole by which it is pierced.

"Now this is what happens to all the vertebrae of the neck, excepting the 7th. Instead of this anterior arch there may be seen on their vertebra (Fig. 8) in most subjects a particular os-

FIG. 8.

FIG. 9.

FIG. 10.

seous piece (A) which does not form a part with the rest of the processes, and which is united by a cartilage to the body of the vertebra. This osseous piece is not disposed as an arch; it proceeds straight outwards, horizontally: if it be met and limited in its growth by the posterior arch, it unites with it through the medium of a carti-

* I have again examined the note with every care, and feel that the details cannot be depended on: notwithstanding my urgent request not to do so, the osseous part represented in the figure was hastily cut from its connexions before I had time to examine what they were. For my own part, I believe that the specimen is one in which the cervical rib extended to the *sternum*, but this cannot be positively affirmed. It may be a partial fusion of the first and second thoracic ribs.

lage which unites with it. By uniting with the posterior arch it forms with it a transverse process, similar to those of the other cervical vertebræ, and which, like them, is pierced by a foramen. But if this osseous piece or bone A (piece de traverse) increase rapidly, and is not checked by the posterior arch, it passes beyond it, it extends itself, and assumes the form of a rib: then the posterior arch B has merely the form of a transverse process, similar to those of the dorsal vertebræ. What I mean may be easily understood by examining the preceding figures, or by examining the skeletons of several children who may have lived only a few months, although occasionally the same thing may be met with in those who have lived to the 6th or 7th year. I have skeletons in which the bone I speak of projects beyond the posterior arch only a few lines; others in which it is more extended, as in Figs. 10 & 11;

FIG. 11.

and finally others, in which it is wholly formed, as in A.

Thus every man may have 26 ribs, and the two additional ribs will depend on the mode in which the bone I have just described meets the posterior arch of the transverse process of the vertebra. If it extend beyond it, it becomes a rib, and the posterior arch is then formed like the transverse processes of the dorsal vertebræ. This rib being moveable, the cartilage which would have united it with the body of

FIG. 12.

the vertebra, and that which would have united it with the posterior arch, remain flexible. If this bone, however, be restrained by the posterior arch, we have then a transverse process formed, like the transverse processes of the other cervical vertebræ, with a foramen or hole piercing it as in the rest."

I have thrown into a note* M.

* "I may remark incidentally, that when this foramen is met with in the 7th vertebra, I have never seen the vertebral artery pass through it.

"If the idea I have just proposed be correct, supernumerary vertebræ ought always to belong to the last cervical vertebra, or, if you please, the supernumerary rib ought to be called the first rib; then we shall have 13 dorsal vertebræ, and 6 cervical. This is what we see in those skeletons I have, which possess 26 ribs. The anatomists who have spoken of the supernumerary ribs have neglected to say where they are placed; nevertheless I do not mean to assert that supernumerary ribs may not be found below the other ribs; there may exist a structure unknown to me capable of giving origin to ribs so placed. However this may be, it appears certain that supernumerary ribs, or those above the number 24, can only be the result of a particular development, and that they do not exist as the others in the germ. In fact, it is evident from my quotations from other authors, that there is sometimes a supernumerary rib for each side of the body, and sometimes it is found only on one side; that sometimes in adults, where all the parts which naturally exist have acquired their full extent and complete development, one of these supernumerary ribs may be perfect, and the other imperfect.

"I am well aware that what I have just said does not explain the reason of the form which this rib takes, of the cartilage in which it terminates anteriorly, and of the intercostal muscles, if there be such, between it and the rib which follows: but I do not think that this necessarily destroys my explanation," p. 539.

Hainauld's remaining observations, which are greatly to the point, providing him to have been a most acute observer; and shall now proceed to complete, in as far as I can, the history of the cervical rib in man, which M. Hainauld's observations assuredly do not fully complete. And first I may observe that he is the only person, in so far as I know, who has seen the "cervical rib" extend to the sternum; the preparation might possibly be still found in Paris, but I imagine it to be *unique*; I never saw nor heard of one any where myself. In fact, in such a case, the 7th vertebra is no longer a cervical one in any sense of the term. But be this as it may, it shews clearly

the correctness of M. de Blainville's view of this vertebra, namely, that it belongs to a category differing from the preceding cervical; a different *group*, *in fact*, which, limited to a single vertebra in man, may one day be found more numerous in some other mammals recent or fossil. But I need not dwell on this here, seeing that it falls to be discussed more fully when speaking of the bradypus or sloth.

That M. Hainauld's view of the mode of formation of the cervical rib is not quite correct, is proved, I think, by the following figure drawn from a preparation which has been now described by me in my lectures for at least 17 years—proving a fact which seems to have been

FIG. 13.

unknown from the time of Hainauld to that of Meckel, for the same error is repeated by Meckel in his latest works. I repeat, the actual osseous elements or germs of this 7th vertebra are more numerous in man than these anatomists supposed them to be, as is fully proved by the above figure, so that no more need be said about it. This is a question totally independent of theory, and is decided by direct intuitive inspection. The pedicle or foot-stalk of the transverse process of this vertebra may, and probably always does, comprise the following elements: 1st, a germ for the posterior arch; 2d, one for the anterior; 3d, a short nucleus for the articular surface; 4th, a separate and distinct germ for the rib. Now these different germs may, and, as we know, are, developed in a great

variety of ways. Sometimes the rib extends to the sternum, so at least says M. Hainauld; more frequently it stops short, and terminates by a rounded free extremity, or unites with the first true rib, forming that process on the inner edge of the rib so curiously described by the descriptive anatomist: sometimes it is very short and rudimentary, but still distinct from the anterior root of the transverse process; at other times so intimately united with it that there is no distinguishing between them. Lastly, the rib may be wanting altogether, and so may the anterior root of the process; or this latter may be wanting, and then the rib seems to take its place by completing the foramen: it was this that misled Hainauld.

In this preparation (which I shall

describe more carefully afterwards) there are two supernumerary ribs, one on each side, but irregularly developed.

With a view to render the history of

the cervical rib as complete as I can, I beg leave to subjoin figures and descriptions of the following preparations:—

FIG. 14.

The whole of the cervical vertebrae, and five superior dorsal vertebrae, in a young person (about five years old), together with the first true or sterno-vertebral ribs. The transverse processes for the 7th cervical vertebrae have been shaded deeply, in order to bring out the following facts. 1st. The great length and irregular form and breadth of both, and their widely different character from the transverse processes of the preceding vertebrae. 2d. On the right transverse process, anteriorly, there is evidently a rudimentary rib, resting on a projecting process of the body of the vertebra: behind this rib there is a large vertebral foramen or hole, through which, in all probability, there passed merely the vertebral vein and a branch of the sympathetic nerve: behind this is the posterior root of the transverse process. 3d. On the other side, or connected with the left transverse process of the same vertebra, there is, first, a distinct rib, separated from the anterior root of the transverse process by an evident fissure: behind this fissure we find the anterior root of the process; and behind this the usual foramen for the vein, shut in posteriorly by the posterior root of the transverse process. The reader's attention is particularly requested to this fact; it refutes Meckel, Hainauld, and all their followers; thus leaving no doubt as to the nature of the structures, and disproving, in respect to the spurious or cervical ribs, what I had

long ago done in regard to the true ribs, that even they were not merely the anterior roots of the transverse processes—a theory which, if not originally brought forward by Meckel, at least was chiefly supported by that laborious anatomist. It ought, perhaps, to be further mentioned, that these transverse processes I have just described do not resemble any of the preceding transverse processes: they have more the character of the same processes in the dorsal vertebrae. Were the rudimentary rib removed, for example, on the right side, we should then have a transverse process without a foramen, with a strong blunted termination turned somewhat backwards, as in the dorsal vertebrae, and a small projecting process (the part supporting the head of the cervical rib) anteriorly, arising from the body of the vertebra, and resembling, were it prolonged, the anterior roots of the transverse processes higher up; so that the anterior roots of the transverse processes of the cervical vertebrae generally seem to me to be formed of these parts—1st, by the facets, which, lower down, support the heads of the ribs; and 2dly, by the delicate nucleus, or germ, which, at first cartilaginous and afterwards osseous, stretches outwards to form the anterior margin of the foramen for the artery, and united by its extremity with that of the posterior root. The left transverse process resembles, when examined from behind, one of the dorsal,

but besides this it has a foramen for the vertebral vein, and an anterior root, perfectly distinct from the head and neck of the rudimentary rib laying in front of it. To this curious fact, the resemblance of the transverse processes

of the seventh cervical vertebra in man to the dorsal processes, I here beg leave to call the attention of anatomists, and shall, in a future part of the memoir, again call the attention of the reader to it.

FIG. 15.

FIG. 16.

These figures represent a very interesting case of the presence of a rudimentary or cervical rib on the right side; also the first, or true thoracic ribs, seen from above; and give a view of the two lowermost cervical vertebræ, and first and second dorsal seen from the right and left sides. As the figures speak for themselves, I shall only mention in detail a few particulars regarding the last cervical vertebra, and conclude by giving a history of the dissection of the soft parts, which, very fortunately, I had an opportunity of observing.

It is on the right side that we find the cervical rib was carried: there is no foramen, properly speaking; the transverse process is unlike the cervical, and is rounded, and slopes back nearly as much (but not quite) as the same process in the first dorsal vertebra. There is a most distinct articular facet on the body of the bone, and a half facet upon its inferior edge; and, lastly, it carried the cervical rib.

FIG. 18.

The ascending extremities, vertical processes of the body (still more remarkable as we proceed higher) of this vertebra, by means of which the bodies are, as it were, locked into each other, is more distinct than what we find upon the first dorsal, wherein this peculiarity in the form of the bodies has all but disappeared. I had almost forgot to mention, that on the right side the transverse process has a distinct articular surface for the tubercle of the rib.

On the left side of the same verte-

bra, the view is entirely different, so that, were the bone sawn vertically, dividing it into two equal parts, no one would ever imagine that the two halves belonged to the same bone. First, in respect to length, the transverse process equals that of the right side, but it is neither so regularly formed, nor so strong; moreover, it has nearly all the characters of a cervical vertebra in this respect: there is a large foramen for the passage of the vein, a deep groove, &c.; and if the germ of a cervical rib did ever exist, it must have disappeared in the very earliest condition of the fœtus, and uniting, by bony union, with the anterior process, has left scarcely a trace of its existence. 2dly, The direction of the process differs from that of the sixth cervical, and of the first dorsal—that of the latter being backwards, that of the former slightly forwards. In its direction, the process I speak of is intermediate to these, or directly outwards.

The history of the dissection of the above case, as transcribed from my note-book, is as follows:—

“During the dissection of a young woman (about 27 years of age) a peculiarity was observed on the right side, where it was evident that there exists a supernumerary rib. The sacro-lumbalis sends a tendon to its tubercle; also the longissimus dorsi, the trachelo mastoideus, and transversalis colli. The scalenus posticus is as large as the medius, and is attached to the first thoracic, or true rib, by a broad surface of about three quarters of an inch in breadth. On removing this superficial portion, a second was found, attached in a similar fashion to the cervical or supernumerary rib. The arteria transversalis colli passed through between the scalenus medius and posticus, over the top of the cervical rib, about an inch from its tubercles. A distinct intercostal muscle occupied the space between the cervical rib and first or true thoracic rib, and the other, or sternal end of the former, was connected or bound to the cartilage of the latter by a strong ligamentous cord. The subclavian artery and first dorsal nerve ran over the upper surface of the cervical rib, and, as usual, between the scaleni muscles. The subclavian vein ran across that tendon or ligament which connected the cervical rib to the cartilage of the true rib. The scalenus

anticus was attached, 1st, to the cervical rib near its extremity; and 2dly, to the first or thoracic rib by means of the tendinous or ligamentous cord already described. The vertebral arteries entered the foramina in the bone of the transverse processes of the sixth cervical vertebrae on both sides." The preceding rough sketch, Fig. 17, also taken from my note-book, may be of use in aiding the above brief description. The subclavian intercostal artery was small; the first aortic intercostal supplied the first normal intercostal space; it anastomosed with the subclavian intercostal.

In fig. 18 I have represented the cervical vertebra in an adult skeleton. Of this preparation, and of the one which follows, I shall speak more particularly in the supplement; the supernumerary ribs were, in this case, two in number, one on each side, nearly symmetrical; the vertebra which carried them strongly resembled a dorsal vertebra.

FIG. 19.

This, also, is taken from the adult, and forms a contrast to the preceding preparation. On each side of the seventh cervical vertebra there is a pretty large supernumerary rib, but quite irregular, and united by bony union to the anterior root of the transverse process of the seventh vertebra. There are two foramina on one side, and one on the other. All the osseous tissue is to be understood to be quite healthy, excepting in those cases where the contrary is expressed.

[To be continued.]

MR. LEE
ON
BELGIAN MEDICAL INSTITUTIONS.

Colony of Insane at Gheel.

ANTWERP possesses a handsome military hospital, and the civil hospital St. Elizabeth, which, like most others in Belgium, is an ancient edifice, formerly a convent,

the chapel of which now forms the principal ward, the other wards being low and indifferently ventilated. The number of beds is about 350. Two physicians and a chief surgeon perform the medical duties. Among the cases at the period of my visit, there were none that seemed to me particularly worth noting.

In my last, I alluded to the exclusive treatment of the insane by moral means: this is carried out on a large, though somewhat rude scale, at Gheel, a village some leagues from Antwerp, where numbers of the insane are placed, to lodge with, and to share the labours of, the inhabitants. As this colony has not been heard of by the great majority of the profession in England, some details respecting it may not be unacceptable, for which, as I have not myself visited the place, I must be indebted to a *brochure* lately published by Dr. Moreau, physician to the Hospice of Bicetre, who kindly sent me a copy of it from Paris.

Gheel is situated in an extensive district of Belgium known by the name of the *Campine*, the plains of which are uncultivated, covered with brushwood and fir trees, except in the immediate neighbourhood of the towns and villages, where the land is in a high state of cultivation. The Campine has been termed the Siberia of Belgium.

Gheel is in the centre of this tract of country, isolated, separated from other habitations by an extent of several miles of waste land, which greatly facilitates the superintendence of the patients, inasmuch as, from the difficulty of progressing through the brushwood, those who attempt to escape must follow the high road, on which they are easily recognized and stopped. At Gheel, the insane, who were formerly treated elsewhere in so barbarous a manner, have, during several centuries, lived almost free in the families of the inhabitants, under the patronage of the saint by whose means they expected to be cured, traditions agreeing in ascribing the origin of the colony to the martyrdom of the daughter of a king of Ireland, who sought refuge in the neighbourhood of Gheel, at the close of the sixth century, to escape the persecution of her father, and who, after her death, was canonized. For a long period there was no other physician in the colony; and, nevertheless, the prayers of the families were sometimes

heard, and cures were effected. In those times of ardent faith, religious practices were calculated to exert an immense influence over the mind of the patient. At the present day, however, recourse is had to Saint Dymphne in order to obtain a patient's cure, in those cases only when a wish to that effect is formally expressed by his family.

The reputation of Gheel as regards the cure of insanity has always stood high, and the miracles operated in their favour by means of the intercession of the Saint, attracted patients from all the surrounding countries. The colony, however, has only been well known since the eighteenth century, at which period it was visited by distinguished men from other countries, among whom was the worthy successor of Pinel, Esquirol, whose principles, as exposed in his *Traité des Maladies Mentales*, were doubtless partly derived from his inspection of Gheel. An asylum, says this distinguished physician, ought to resemble as much as possible, by the disposition of its localities, ordinary habitations. All that savours of constraint or mistrust, all that might excite in patients the thought that they are for ever separated from society, ought to disappear. The classification of the patients according to the nature of the alienation is one of the most important conditions of the treatment. Hence the necessity of numerous divisions, which admit of the avoidance of confusion. The colony at Gheel is but the realisation of these principles, the essential basis of all treatment; and there, as is always the case, facts have preceded theory; chance has gone before the discoveries of science.

In 1803, M. de Ponteconlant, the prefect of the Dyle, who was doubtless struck with the immense advantages which the colony presented for the placement of the insane, thought, as he expressed himself, that he fulfilled a duty towards humanity in adopting, with reference to these unfortunates, a refuge recommended by the success of long experience. He consequently caused all the insane in the hospitals at Brussels to be sent there; and the example was soon followed by Malines, Louvain, and other towns of a secondary class. When Belgium was united to Holland, in 1815, the eastern provinces and Flanders sent a considerable

number of insane to Gheel. Lastly, Namur and Luxembourg made arrangements with the municipality of Gheel for the reception of other patients.

While the colony was making so rapid an increase, its interior organization ought at the same time to have been duly considered, and means should have been taken to regularise so great a number of individuals. Unfortunately it was not so; Gheel was only a *depôt*—a sort of Botany Bay—to which Belgium sent those patients who, after having been treated for a few weeks in one hospital or another, were reputed incurable. They were there forgotten; and those only left the place who, being restored to health, and conscious of their cure, were permitted to return into society.

"It is very true, as stated in the report made to the Communal Council of Gheel, on the 19th November, 1838, that this state of matters has, at all times, awakened the solicitude of the magistrates of the commune; but most of the police regulations were out of date, and had fallen into disuse. Serious abuses had crept in; the direction of more than 700 insane was, so to speak, committed to chance. The same neglect occurred with reference to the administrative and medical departments: the insane were placed in the colony, and quitted it cured without the knowledge of the authorities; no account was given of the patients by their families; methodical treatment had become impossible; the colony was a vast field of observation, uncultivated and useless to science."

The censures expressed in the public papers, by foreign and Belgian medical visitors, caused the institution to fall into a well-merited disrepute, and even compromised its existence; a serious and radical reform had then become indispensable; and the Council consequently adopted, in 1838, a police regulation of administration and superintendence, upon the basis of a medical direction.

There are no less than 9000 inhabitants in the commune of Gheel, a large portion of whom reside in hamlets at a greater or less distance from the central village. The insane (men and women, the number of which is about equal) are distributed over all the parts of the district. All the inhabitants, whatever be their position or avocation, may

receive patients into their houses, according to agreements made with their families, or from the hospitals of Brussels, Malines, &c. Most of the patients are supported at the expense of the government. The price required for board and lodging varies according to the accommodation. It seldom exceeds 300 florins annually, or is lower than 100. Each patient is placed under the direct superintendence of the person to whom he is confided; this individual (*nonricier*) must supply the patient with wholesome and abundant food, a clean and well-aired lodging, a good bed, &c.

No insane person can be placed at Gheel without being provided with a preliminary authorization of sequestration.

Monomaniacs, with an evident tendency to homicide, or to incendiarism, are not received at Gheel.

All the insane are inscribed upon a register on their arrival, together with such details and peculiarities of their case as could be obtained. In such an establishment the superintendence must be active, unceasing, prompt in chastising offenders, and in encouraging good actions. It must have an eye, day and night, upon the patient and the person to whom he is confided. Doubtless this superintendence cannot be so easy in a colony as in an asylum; but being shared by a sufficient number of individuals, and developed in its means of action, it will be able, without difficulty, to repress abuses, to protect each member of the colony against the neglect or ill-treatment of his host, no less efficiently than in establishments where the patients are trusted to *infirmiers*. There is no patient at Gheel who has not a commission of superintendence, or a director, to watch over him. The general superintendence is vested in the local administration. The hospices, towns, parishes, or private individuals, who place patients at Gheel, may appoint special commissions of superintendence, or may nominate individuals for the purpose, at their own choice and expense: these special superintendents are, however, under the control of the College of Burgomasters.

The different members of the commissions are charged to visit the patients frequently, and without previous notice: the entrance of each

house is at all times open to them. They see the patient, inspect his room, his bed, receive his complaints; in a word, obtain all the information which may conduce to ameliorate his position. If the host is in fault, the patient is removed and placed with another. Should he have struck or ill-treated his patient, unless he can prove that it was done in his personal defence, he is declared *infamous*, and unfitted to receive any more lodgers. The insane share the labours and the daily occupations of the families in which they reside. Some even contract such a liking to the mode of life that they voluntarily remain after having recovered their reason. The majority walk about the village and in the environs, with almost as much freedom as the other inhabitants; but in accordance with the regulations, they cannot go out before six in the morning in summer, and eight in winter: they must return home at four in the afternoon in winter, and at eight in summer. Each *nonricier* is bound to enforce this regulation under the penalty of a fine. Those individuals, however, who are known to labour under a harmless kind of alienation, and whose conduct is peaceful, are exempted from the strictness of this law; but in no case are they allowed to be out at night. Each patient going to church is accompanied by a member of the family.

With the exception of these restrictions, the patients enjoy all the advantages of society, of which they are even useful members. In fact, the colony supplies hands for agriculture, for various industrial pursuits and professions, while, at the same time, the mind of the patient is diverted and occupied, which cannot fail to contribute powerfully to their restoration. There are at Gheel not merely workmen of all kinds, but even teachers of languages, of arithmetic, drawing, and writing. There is a harmonic society, which was founded by one of the patients. "I assisted," says Dr. Moreau, "one evening at a vocal and instrumental concert, and was struck with the precision and the unity of the execution."

The entrance to the smoking houses is not prohibited to the patients; and it is not uncommon to see them there quietly smoking their pipe, with a pot of beer at their side; or playing at

cards, billiards, or some other game. Abuses are prevented by fining the inn-keeper in whose house a patient may have become intoxicated.

"Although," continues Dr. Moreau, "I have had much practice with the insane, and have, since 1827, lived almost constantly among them; although I cannot forget that, every day, at Charenton, thirty or forty patients, of both sexes, meet in a public room, where music and different games procure them agreeable diversions, yet I confess I was surprised to see them at Gheel, walking about freely in the streets of a large village, and in the country, mixed with the inhabitants. I was especially surprised at the little notice which they attracted even from the children, whose attention is not excited by the extravagances of some of the patients at Gheel: one is born, so to speak, a superintendent of patients. It is *traditionally*—by the experience of predecessors—that the wants of the insane are known; the art of ruling them, which is so difficult, the Gheelois possess, in great measure, without being aware of it; because it forms part of the habits of their lives. The great liberty which the insane enjoy at Gheel cannot then be attended with much inconvenience, since, after all, they are constantly watched by numerous and intelligent keepers.

In our hospices, high walls, a strict superintendence, keepers placed at the entrance of each division, are not always sufficient to prevent evasion. With what perseverance do not almost all the inmates ask for their liberty! how greatly do they not torment and agitate themselves in order to regain it! Hence it is natural to suppose that the number of those who escape from Gheel would be large; and yet it is only, on an average, seven or eight annually, out of more than seven hundred individuals. This number is so small that it might be supposed incorrect if the statistical returns for several years did not confirm its truth. On considering, however, the disposition of the insane, there is nothing to occasion much surprise as regards this point: the patients at Gheel perceive that they enjoy almost as much liberty as the inhabitants whose employment they share. Whatever be the ideas they may entertain as to the causes which brought them to the place, the idea of

a prison—of forcible detention—does not arise in their minds so easily as when they are shut up in the courtyard or sleeping-wards of an hospice, together with other individuals subjected to the same regimen and to a uniform mode of life. The privation of liberty being scarcely felt, they do not think of forcibly obtaining a good which appears to be at their disposal. Precautions are, nevertheless, taken against escape. If a patient manifests a fixed resolution to run away, or has already made the attempt, he is not on that account constantly confined in a room; but a rather heavy chain, the ring of which is covered with leather, is fixed to his leg, so that he still enjoys considerable liberty in walking about.

Those patients who exhibit a disposition to suicide, and epileptics, are subjected to a special superintendence. Suicide is rare in the colony, which is more to be attributed to the mode of life, the continual occupation, and the degree of freedom enjoyed, than to the direct superintendence. One patient killed himself in 1840, and one in 1841.

Those patients who are violent and dangerous are placed out of the way of others; but these cases are rare in the colony; the reason of which is to be found in the liberty which they still enjoy, notwithstanding their state of excitement, and which the nature of the locality admits of. It is now known that the best means of calming the agitation, the fury, of a maniacal patient is to allow him, as much as possible, freedom of action. This agitation, this fury, inevitably increases in proportion to the efforts which are made to repress it, and ultimately terminates in incurable stupidity. When, however, a patient is unmanageable, the *camisole*, or even chains, are allowed to be made use of at Gheel, upon the representation of the physician to the administration that these means are requisite.

[To be continued.]

ACUTE PERITONITIS.

To the Editor of the Medical Gazette.

SIR,

THE subjoined case of acute peritonitis, induced by the reception of several blows upon the back, is not devoid of interest: the length of time which elapsed between the infliction of the

violence and the supervention of inflammatory symptoms, coupled with the situation of the pain in the abdomen, inclines me to the opinion that partial laceration of the longitudinal ligament of the liver was the immediate consequence of the strokes: but to trace the relation of cause and effect I leave to those philosophic minds under whose consideration this report will fall, should it be deemed worthy a place in your valuable journal.—I am, sir,

Your obedient servant,

J. W. WAINWRIGHT, M.D.

Manchester, Oct. 16, 1843.

Mrs. G—, æt. 36, of plethoric habit of body, states that on Friday, Sept. 29th, whilst sitting on a low chair, she received three or four severe blows from a person's fist, which prostrated her on the floor. Was not deprived of consciousness, but was immediately distressed by violent retching; some tea, of which she then partook, was at once rejected. No marks of discoloration perceptible on the back, though the pain was dreadfully harassing; urine passed without inconvenience.

On the 4th of October, on the recommendation of her medical adviser, leeches, to be followed by warm fomentations, were had recourse to: the pain extending round the abdomen, with incessant vomiting, induced the medical gentleman to prescribe calomel and opium, with effervescing salines. The vomiting, however, continued unabated till the 7th, when it was fortunately relieved by the exhibition of prussic acid.

At this period she began to complain of acute pain and tenderness about the junction of the epigastric and right hypochondriac regions, to relieve which leeches were applied with success.

On the 8th Oct. in conjunction with her medical attendant, the case first came under my observation. On entering the room, we found the patient propped up in bed; knees semiflexed; face pallid, with intense anxiety depicted on her features. Skin dry and harsh; pulse 140, small and compressible; tongue slightly furred, with dusky-red edges; thirst much complained of; intolerable pain over the thin margin of the liver, with inability to bear the least pressure over any part of the abdomen; respiration quick and hurried, performed entirely by the

thoracic muscles; sickness has not returned since the administration of the hydrocyanic acid. Urine high-coloured; stools dark and watery.

A large number of leeches were ordered; calomel and opium every second hour; with draughts of prussic acid to allay the irritability of the stomach.

9th.—Patient lying in the same position as yesterday; face much flushed; features expressive of intense suffering; has had no sleep from the acuteness of the pain, which has shifted into the right iliac region; more leeches had in the night been applied to this spot without alleviation; pain more intense over the whole abdominal cavity, which is tympanitic; tongue covered with a dry, brown fur; still complains much of thirst, for which she prefers weak tea to any other beverage. Bowels unmoved during the last 24 hours. Urine scanty, high coloured, with deposit of a copious sediment. Pulse 140, small, and weak; respiration performed with fear, as it augments the pain; no sickness since last report; skin dry.

Venæsectio ad ℥xij.; six grains of Calomel, and Pulv. opii. gr. iij. to be taken immediately. A purgative enema exhibited, and a powder of Hydrarg. chlorid. gr. j., Pulv. Scammon, gr. iv., to be taken every second hour.

In the evening, patient more composed, countenance indicative of less pain; position now horizontal; has been much easier since the bleeding; pain in iliac region mitigated, still unable to bear the slightest pressure; tongue moist; blood buffed, and very much cupped. Pulse 90, soft, and full.

V.S. iterum ad ℥xvj. continuentur Pulveres. Mistura Purgans vice Misturæ Acidi Hydrocyanici. Expl. cantharidis lateri applicandum.

10th.—Looks better; more free from pain; has passed a comfortable night; skin moist, perfectly easy, unless pressure be made over the abdomen; tongue tolerably clean; thirst still urgent; has vomited once; three copious bilious dejections have been passed; pulse 90, soft, but firm. Respiration natural; can take a deep inspiration with little inconvenience. Blood as much buffed and cupped as the former.

Continuentur Pulveres, et habeat Magnes. Sulphat. ℥ij. in aqua Menthæ pip. cum singulo pulvere.

In the evening the patient still improving, her only complaint being of excessive thirst; pulse 120, irritable.

Ordered an opiate.

11th.—Passed a comfortable night; no pain; pulse 86, full; bowels thrice relieved.

Omitte Pulveres.

Mouth not perceptibly affected by the mercury.

12th.—Recovery proceeding rapidly: complains of exhaustion from a diarrhoea which set in at 3 A.M., up to which time she had enjoyed sound sleep, without the aid of a sedative. Alvine dejections watery, and bilious. Pulse 84.

Broth or farinaceous food recommended.

To take a mixture of the aromatic confection, with a few drops of laudanum in each dose.

From this time her recovery was uninterrupted, without the supervention of a single unfavourable symptom.

MATICO.

To the Editor of the Medical Gazette.

SIR,

DR. R. W. SCOTT has, in your last number, shewn a filial-like jealousy about Dr. Jeffreys' share in the merit (?) of introducing the matico into practice. In his extraordinary desire to manifest this jealousy, he has created a shadow merely for the purpose of displaying his quixotism.

He complains of my having omitted, in my notes on the matico, all mention of Dr. Jeffreys, and says that "it might be inferred from Dr. Lane's communication that *he* was the first to make trial of its internal use;" and then proceeds to insinuate that I was indebted to Dr. Jeffreys for the matico which I employed; next, that I was aware it had been previously used internally; and lastly, that I have been filching from Dr. Jeffreys' "fair fame" as the introducer of this plant.

As I knew nothing of Dr. Jeffreys' labours in connection with the matico, except as a person who had interested himself in its importation and employment certainly not as a physician who had ever had the opportunity of testing its internal medicinal action, I

saw no reason for introducing his name any more than that of the druggist supplying the article to the hospital.

What was assigned as the motive of my trying the virtues of this plant may here be repeated as true at the present moment:—"I am not aware of their (the leaves) medicinal action when internally administered having been ascertained;" and it may be added, nor am I aware, except from Dr. R. W. Scott's announcement, of its having been essayed in this country. Yet, excepting the Edinburgh Medical and Surgical Journal, I regularly see, at their respective periods of publication, all the accepted standard and esteemed medical journals. The Transactions of the Provincial Medical Association, however, not being included in this catalogue, may explain and show that it is *not* "rather singular that Dr. Lane should state that he was not aware that it had hitherto been employed internally." If Dr. Jeffreys choose to bury his productions, he must not expect others to exhume them merely for their coffin plate.

The only notices that I have been able to find of this plant in any of the English medical journals were two—the brief announcement of its existence (for it cannot be called a description), its styptic property, and a promise to try its reputed diuretic action, published by Dr. Jeffreys*; and Dr. Monro's† account of his experiments regarding its stypticity. Wherefore, so far as English medical records go to prove a priority of its internal administration, they would favour my claim were I to affect to institute one. I should not commit such a folly. The plant has, as is stated in my notes, long been internally administered and externally applied by the Peruvians. Where, then, the merit in doing that which has elsewhere so often been done before? My object was "to give the plant that honest and impartial trial which its Peruvian reputation would seem to invite and justify." This I have been realizing, ignorant of the labours of any others in the same inquiry. To me priority of discovery of such a comparative trifle is unimportant. If Dr. R. W. Scott think that his client, Dr. Jeffreys, can derive

* *Lancet*, vol. i. 1829, p. 567.

† *Prov. Med. and Surg. Journ.* June 18, 1842.

from his exertions on behalf of the importation and employment of the matico a hope of the glimpse of professional immortality, he is most welcome to the merit of priority, as I can better afford to spare than he to lose the advantages of such a chance.

Mr. R. Hinde, of this town, about four years ago, first made me acquainted with the matico. He had seen it used by the Peruvians, and was very anxious to have its properties known in this country. In giving me a specimen, sadly too small to serve any useful experimental purpose, he spoke in highly laudatory terms of its efficacy as an astringent, &c. when internally or externally used. Being unable to obtain an additional quantity, I was prevented from effectuating his wishes. About the latter months of last year, however, having learned that Dr. Jeffreys was in some way connected with the importation of this plant, I requested Mr. C. Ricketts, the house-surgeon of the hospital, to inquire where it might be obtained. An answer was received, with so much of the herb as could be inclosed in a penny letter, accompanied by a circular advertising the place of sale of the matico. The quantity forwarded was so insignificant, that Dr. R. W. Scott ought to have known, if properly instructed by his client, that it could not have enabled me to have made a single experiment with it. The hospital was afterwards supplied by the druggist advertised in the circular, and subsequently by a highly respectable chemist in this town.

It may be here necessary to remind Dr. R. W. Scott, that in claiming the *priority* of merit, it is always of paramount importance to be accurate in dates. He has in the MEDICAL GAZETTE stated that Dr. Jeffreys had some correspondence with Mr. Ricketts in 1841. In the Medical Times he has been more particular, and specified the month as well as year, viz. October, 1841, as the date of this correspondence. Now, no correspondence on this subject, nor, I believe, any other, took place between these two gentlemen for at least a whole year afterwards!! This is absolutely unimportant, except as a lesson to Dr. R. W. Scott, teaching him that when he next becomes advocate he must see to the correctness of his instructions ere he employs them in

public. Dr. Jeffreys, in a month after transmitting his "note" of the matico, wrote for the results of the employment of this medicine, when Mr. Ricketts replied that Dr. Hunter Lane was engaged in trying its efficacy in diseases depending upon relaxation of the secerne capillaries. I saw no reason why I should report to Mr. Jeffreys the result of my experience. I preferred to do it to my professional brethren generally. Because I have done it thus independently, and not under the wing of one who could never constrain my respect, I am accused of attempting to steal the merit of priority in introducing or internally using the matico. Dr. R. W. Scott may be assured, that, if disposed to commit literary or scientific larceny, I should select as my victim one who could afford to lose.—I am, sir,

Your obedient servant,

J. HUNTER LANE.

—
Medico-Chirurgical Transactions, published by the Royal Medical and Chirurgical Society of London. 2d. Series. Vol. VIII. Longman and Co. 1843.

THE volume which lies before us contains various interesting and valuable papers, of which we proceed to present our readers with a brief analysis, taking the essays in the same order as we find them.

Case of Paralysis, without loss of Sensation, from Disease of the Cervical Medulla. By JOHN WEBSTER, M.D. Consulting Physician to St. George's and St. James's Dispensary, &c.

It is gratifying to observe the attention which has of late years been given to the nervous system practically as well as physiologically, and we must say that much of this is owing to the investigations of Sir Charles Bell, followed up as they have been by various others.

We give the essential particulars of Dr. Webster's case in his own words.

In the year 1836, Mr. G——, whose health had hitherto been excellent, was annoyed for some months by a phagedenic ulcer on the left leg, from

which he suffered much pain and inconvenience; and although the sore afterwards got well, a similar ulceration on the leg again broke out in 1838, when it was followed, in the same year, by a large chronic ulcer on the posterior part of the pharynx. It is right, however, to state, that this local affection did not appear to be of a syphilitic character, and the patient, I was assured, never had any complaint of that nature. The ulceration in the throat continued for some time without undergoing much alteration in appearance; until, both from it, and from the sore leg, the patient's constitution was considerably deteriorated; and as Mr. G—— afterwards met with a severe domestic affliction, he also suffered much from mental depression.

Towards the end of autumn in 1839, Mr. G—— again began to suffer materially in health; he now complained of almost constant pains in the head, which occasionally became so severe as even to oblige him to stop in the street, and to lean against the rails for support. These symptoms were also frequently accompanied by sickness and considerable prostration of strength; the bowels being generally costive, the tongue much furred, and the appetite at the same time impaired. In January 1840, slight epileptic attacks now supervened, which were attended with an exceedingly slow pulse, varying generally from 35 to 40 in a minute. From this distressing state, Mr. G——, however, recovered so much, as to be able to leave home about the end of February, and soon afterwards to resume, in some degree, his ordinary professional avocations.

In the following March, notwithstanding the above improvement, he was again attacked by several epileptic fits, but of a much more marked character than any of those noticed previously.

Subsequently, that is in the summer of 1840, Mr. G—— complained of considerable weakness in the back and loins, accompanied with pains of the head, and in the nape of the neck. He soon afterwards became unable to walk steadily without support: and, to use the patient's own words, "he felt as if his body were cut in two, and the lower half falling away from the upper." Both hands and arms now became very weak, and were soon nearly powerless;

and he also complained of considerable pain about the fourth cervical vertebra, increased in severity on merely bending his head backwards; but this sensation felt however less painful when rotatory motion of the neck was only attempted.

About the end of autumn in 1840, as most of the symptoms had gradually undergone material alleviation, compared with their former severity, the patient seemed now greatly recovered in strength, and could walk out occasionally, with only the aid of a staff. Indeed, towards the end of that year, the progress made was so far satisfactory, and the general health apparently so much restored, that Mr. G—— was even able to visit his friends and join a little in society. During this temporary amendment, having dined at Kensington, on Christmas-day, he was afterwards, in consequence of not meeting with a conveyance, unfortunately obliged to attempt walking to town, during a very cold and frosty night, when the streets were covered with snow. From the great exertions Mr. G—— made on this occasion, he soon got so fatigued, that being totally unable to proceed the whole way on foot, he was taken home in a carriage, chilled and completely exhausted.

After this misadventure, all the symptoms from which Mr. G—— had previously suffered for a long time so peculiarly, again became as marked and severe as before, until the ability of moving any of his limbs got at last so very feeble, that eventually he was entirely deprived of the use of both legs and arms.

From this time he gradually got worse, notwithstanding various remedies tried by Dr. Webster and others, and died July 22d, 1843.

Autopsy.—The body appeared considerably emaciated, but was not discoloured. Having removed the skull-cap, some effusion of lymph was found under the arachnoid membrane covering the left side of the brain, along with turgescence of that and the other hemisphere; both divisions being pale, and exhibiting a watery aspect, although their texture was firm and compacted. The ventricles of the brain seemed large, particularly the left; and about two ounces of serum were effused in these cavities; the foramen commune being at the same time larger than

natural. The arachnoid tissue extending over the pons Varolii adhered to the parietal layer of that membrane; but no tumor, or any other change of structure, was found either in the brain or cerebellum, excepting that the latter organ appeared anemic, and rather softer in texture than ordinary.

Having carefully laid open the vertebral column, throughout its whole length, the theca, corresponding to the three or four lower cervical vertebrae, was found to be much distended; and on being cut into, the arachnoid cavity, with the sub-arachnoid tissue, appeared filled with lymph, which evidently had been some time effused; as the membranes were thereby united to each other, and also to the cord. On making a more minute examination of the parts, the adhesions of the membranes to the cord were discovered to be much firmer at its anterior than posterior portion; indeed, they were actually so strong as to be inseparable from the medulla without rupture. At this particular part, the medulla also appeared larger than usual, felt soft and pulpy to the touch, and on being divided by the knife its substance seemed to be in an almost diffuent state, infiltrated with serum, but exhibiting a natural colour. For the extent of half an inch above the point just described, the cord had a dusky red tinge, appearing, however, of the ordinary consistence. In the anterior and posterior columns, not much difference was observable to the naked eye at the first superficial examination of the diseased part of the medulla; although both divisions of the cord seemed considerably softened, infiltrated and disorganised, particularly in the posterior columns; whilst as well above as below the affected portion the medulla was healthy, and quite natural in appearance.

Case of Bronchial Calculus, with observations on Disease of the Bronchial Glands. By JOHN CHARLES GRAHAM TICE, M.D.

MR. ALDRIDGE, quarter-master of the 8th Regiment, aged 48, and of plethoric and nervous temperament, complained, September 7th, 1842, of pain in the right side, affecting his respiration to a trifling extent. Pressure over the liver caused uneasiness; the tongue was

furred, and the bowels confined, but the pulse natural. His greatest discomfort was from a disagreeable taste, "resembling fried onions." He was freely purged, with temporary relief; but his discomforts soon returned to become aggravated, especially the factor of the breath, which, however, though so distressing to himself, does not seem to have been perceptible to others.

Cough and dyspnoea now came on, and the only posture in which he obtained any degree of relief was leaning forward on his knees. Stethoscopic examination showed nothing amiss either about the lungs or heart, but his voice became hoarse at intervals, and it was suspected that the larynx was implicated. The symptoms rapidly increased, and he died comatose at the end of six weeks from the commencement of his illness. The following appearances presented themselves.

The removal of the sternum was difficult, in consequence of the ossification of the cartilages of the ribs. The right lung was a little gorged with blood and rather dark coloured, but it was free from adhesions, and in other respects perfectly healthy. On raising it and dividing its attachments, the knife suddenly entered a cavity, of the size of a pullet's egg, from which a most offensive odour was emitted. This cavity was formed by an abscess in a mass of enlarged bronchial glands, situated at the bifurcation of the trachea. It opened into the right bronchus, ulceration having destroyed a large portion of that tube. The inferior margin of the ulcerated opening was thickened and elevated: on the other side the abscess communicated with the left bronchus by an aperture about half an inch in diameter, having inverted and thickened edges. Posteriorly, the abscess had made its way into the œsophagus by ulceration. The opening into that canal was capable of admitting a large-sized bougie. The abscess contained a quantity of calcareous matter, some very hard, some of a soft consistence. The whole, when first examined, was of a dark melanotic aspect. A triangular portion of the hard calculous matter had firmly wedged itself into the aperture communicating with the right bronchus. The concretion was found, on analysis, to consist of phosphate of lime.

On Congestive Pneumonia consequent upon Surgical Operations, Diseases, and Injuries. By JOHN E. ERICHSEN, Esq.

MR. ERICHSEN has had an opportunity of making his examinations in 62 cases, and arranges them as follows.

1. Those in which there were unequivocal evidences of pneumonia, amounting to 28; not far from one-half the total number.

2. Doubtful cases, in which the lungs presented the characters common to the first stage of pneumonia and congestion. These amount to 11.

3. Cases in which the lungs were found diseased, but not inflamed or congested. These amount to 9.

4. Cases in which the lungs were healthy, amounting in number to 14.

In the 28 cases alluded to, the right lung alone was affected but three times; the left lung alone also but three times; and both lungs together in not less than 22 cases. With respect to the character of the inflammation of the lungs following surgical operations, in the great majority of cases it is of the asthenic character, being "essentially a pneumonia complicated by a super-added congestion."

In addition to the ordinary circumstances leading to the production of pneumonia, Mr. Erichsen thinks that there are peculiar causes tending to it as a consequence of operations.

1st, Those circumstances which act mechanically, by causing a congestive state of the posterior part of the lungs, as the recumbent posture long continued. 2d, Those causes which act by diminishing the power of the nervous system, such as long-continued and copious suppuration, confinement in the wards of an hospital, and fever, especially of the typhoid type.

In regard to treatment, our author thinks it is of more importance to aim at remedying the state of the nervous system, and preventing congestion by change of posture, than to direct our efforts, as in ordinary inflammation, to the suffering organ. "With this object in view, the energies of the nervous system should be supported and increased by such stimuli and tonics as the patient may be able to bear; as, for instance, carbonate of ammonia, decoction of senega, quinine, and, in

extreme cases of depression, wine and brandy. The inflammatory condition of the lungs should, at the same time, be combated by means of calomel, combined with minute doses of opium, and by counter-irritation in the form of dry cupping, blistering, stimulating embrocations, or turpentine epithems. Blood-letting in any form, whether general or local, is not only contra-indicated by the already enfeebled condition of the patient, but would, to say the least, be perfectly useless."

Researches into the Connection existing between an unnatural degree of Compression of the Blood contained in the Renal Vessels, and the presence of certain Abnormal Matters in the Urine. By GEORGE ROBINSON, Esq. Communicated by MARSHALL HALL, M.D. F.R.S. &c.

MR. ROBINSON published a very interesting paper on "Albuminuria" in this journal last year, to which we beg to refer our readers. The general result of his researches is, that not only albumen and blood, but coagulable lymph or fibrine, escape into the urinary passages in consequence of obstruction of the return of blood through the renal vein; congestion of the blood in the renal vessels is produced, giving rise to phenomena identical with those of the primary effects of inflammation.

An Account of an unusually large Biliary Calculus, voided from the Rectum. By JAMES ARTHUR WILSON, M.D. Physician to St. George's Hospital.

THE calculus here described is "large as a full-sized walnut," and yet, during its passage into the bowel, it excited no pain. The patient was a gentleman aged 73, and he was affected with hiccough and vomiting during many days before the calculus made its appearance.

In less than a fortnight from the first attack (November 1842) the urine and feces resumed their natural appearance, and the skin was no longer yellow. After a time the symptoms returned, and he had frequent fits of sickness, with offensive discharge from the stomach, "black as coffee-grounds." About the middle of December the

bowels, previously inactive, began to relieve themselves spontaneously, and gave passage to a very large biliary calculus, which, on chemical examination by Dr. Belce Jones, proved to consist, in the centre, of nearly pure cholesterine, while, externally, it was composed of inspissated bile, with an admixture of fatty matter or cholesterine.

—
On Fatty Degeneration of the Arteries, with a Note on some other Fatty Degenerations. By GEORGE GULLIVER, ESQ. F.R.S. Communicated by THOMAS HODGKIN, M.D.

THE liability of arteries to be affected with what is called "atheromatous" and "steatomatous" degeneration of their coats has long been known, but the specific nature of these morbid changes does not seem to have been so minutely investigated previously as has now been done by Mr. Gulliver. By the aid of a microscope the following constituents may be observed, viz. transparent crystalline pearly plates, oily globules of various sizes, small earthy concretions, and a multitude of very minute particles, forming a kind of ground for the others. These are best seen when the matter is diluted with water or weak acetic acid. The crystals are cholesterine. There is almost always wasting of the middle coat of the vessel at those points which are near the fatty matter, and some thinning of this coat generally accompanies the thickening of the internal membrane. Ossification of the arteries, or thickening of their lining membrane, is generally attended with the presence of fatty matter between this coat and the middle one, as well as in the substance of both. Two plates are given in illustration, and the following conclusions drawn:—

1. The white or buff-coloured opaque spots of the inner membrane of the arteries are of a fatty nature.

2. The soft matter, which has been generally called atheroma, and which often collects between the inner and middle coats, is also fatty.

3. The fatty matter is frequently found in the substance of both these coats.

4. A fatty degeneration of the tunics of the arteries is generally connected with that state of them which is the

most frequent cause of aneurism, as well as of their obstruction, occlusion, or wasting, in aged people.

5. The matter usually contains cholesterine and oleine, and often some margarine.

6. The tunics of ossified arteries, as well as the bony plates, are often pervaded by the fatty substances just mentioned.

Mr. Gulliver is of opinion that these fatty degenerations act an important part in various diseases, especially consolidation of the lungs "in every variety," and in fatty degeneration of the liver.

—
Remarks on the Calculi in St. George's Hospital. By HENRY BENCE JONES, M.A. Cantab., Licentiate of the Royal College of Physicians. Communicated by CÆSAR H. HAWKINS, ESQ.

THIS paper gives the result of an interesting examination by Mr. Jones of a considerable collection of calculi contained in the museum of St. George's Hospital,—most of which were presented by Sir Benjamin Brodie.

Of these calculi, 233 have been divided; and from the internal structure thus exhibited, it appears that 46 are simple, 49 compound (or consisting throughout of a mixture of two or more substances), and 147 alternating. Of these last, 83 have a simple nucleus and in 58 the nucleus is compound.

If, again, we inquire how often the same substance forms either an outer calculus or a well-marked layer, we find not less than 450 distinct deposits. Uric acid occurs, either alone or mixed with other substances, 135 times; urate of ammonia, 222 times; oxalate of lime, 163 times; the phosphates, 139 times; urate of ammonia with oxalate of lime, 89 times. The urate of ammonia would appear to exist in the urine in a state of health: "the rapid deposit of this substance when urine is evaporated under an air-pump, over sulphuric acid, and the change which ensues if even carbonic acid is first passed through the liquid, admits of no other conclusion." Litmus paper is reddened by the urate of ammonia; and, therefore, the mere existence of that phenomenon does not, *per se*, warrant the exhibition of alkalis.

The presence of the phosphates gene-

rally shews either a neutral or alkaline state of the urine, and our author infers that "uric acid and the phosphates must exist very rarely in the same deposit." Again, it is inferred that the occurrence of the oxalate of lime is independent either of acidity or alkalescence. In only 97, out of 252 cases, was much free acid secreted; or only twice in five cases were alkalies necessary in order to remove the acidity of the urine.

In an appendix an account is given of between 20 and 30 calculi which belong to Mr. Hawkins. One of these proves the existence of cystine at so early an age as two years.

MEDICAL GAZETTE.

Friday, November 3, 1843.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

LATE HOURS IN BUSINESS.

THE unhealthiness of great towns is a constant subject of comment among hygienic writers; and the causes to which it is attributed are both numerous and important. The crowded lodging-houses in which so many of the poor drag on their life—the general adulteration of food—the habit of spirit-drinking, all play their part in this tragic drama. Let the rustic reader, safe and exulting in his home-brewed ale, imagine the effects of porter drugged with opium and *coccus indicus*, and not taken by the half ounce, like a narcotic mixture, but quaffed by the pint and the gallon, as if it were the most innocent beverage in the world!

Again, the anxious mode of life, which is the curse of great towns, the gambling which takes place, not merely at the play-table, but on the Exchange and in the Corn Market, ranks as a

heavy item among the causes which undermine health, and shorten life. It is this anxiety which makes us prematurely old, and anticipates the epoch of gray hairs.

Another obvious cause is the late hours, not merely of the votaries of pleasure, but also of the slaves of business. Mr. Arthur J. King, honorary secretary to an association for abridging the hours of business, has written some pamphlets on this subject, with the zeal of a man thoroughly in earnest. Shops, as our readers well know, are generally open for 13, 14, and 15 hours a day; and to stand behind the counter from 8 in the morning till 10 at night is the lot of unnumbered shopmen and apprentices. The master may retire at 5 o'clock to the comfortable seclusion of his back parlour; but his coadjutors must continue their slavish toil, and stand for five hours longer in an atmosphere contaminated with the gas burned in it. Add to this the unbearable glare of this cheap and "business-like" light, and you will have at least one good reason why the townsman's life is so much shorter than that of his rustic brethren. What with the carbonic acid gas produced by the respiration of the shopmen, and the combustion of the gas, (to say nothing of the carburetted hydrogen gas which escapes unburned,) it must be confessed that the air of our metropolitan shops differs most lamentably from that which passes over ploughed fields and green hedges. Now, the natural method of relieving the flushed cheek and heavy brow produced by these gaseous poisons, would be to walk out into the country. The morning, of course, would be the most appropriate time.

As one who long in populous city pent,
Where houses thick and sewers annoy the air,
Forth issuing on a summer's morn to breathe
Among the pleasant villages and farms
Adjoined, from each thing met conceives delight,
The smell of grain, or tedded grass, or kine,
Of dairy, each rural sight, each rural sound.

But alas ! for him whose duties begin at 8 A.M. there is no morning's walk into pleasant villages ; for the exhausted serf whose duties end at 10 P.M. the only walk is the one up stairs to bed—with the occasional exception of a walk to a divan, for the stimulus of tobacco and whisky.

"A deficiency of exercise," says Mr. King, "is another evil occasioned by the length of the hours of business. At a public meeting held in Wolverhampton, a case was mentioned of a young man in a chemist's shop in Lancashire, who had crossed the threshold of the shop but once in three weeks, and then on an errand of business." Nay more, this enormous practical evil is defended by some theoretically. "It is the avowed object of some to extend the hours of business as long as nature will hold out. It was the declaration of an alderman of London, that he thought bed was the best place for assistants after business." * * *

"Strange that sleep and business—unconsciousness and mechanical performances, should be the only lawful engagements for a man !"

The mind is commonly obtunded in the drooping body ; the intellectual powers gradually vanish, and the poor drudges are taught to believe that there is no other use of the mind than in business, and that education ceases with school days, its only object being to enable them to read, to write, and to cipher for business."

The practicability of the reform proposed depends essentially on the fact that all which is now done in fourteen hours might be equally well done in ten ; in a word, business may be concentrated, instead of diluted. The first objection to the improvement would be that traders are forced to keep their shops open unconscionably late, by the keenness of competition. The answer to

which is, let every shop-keeper join an association pledged to early hours. But some, replies the objector, would not join the association, or, having joined it, would break their agreement, and thus run off with the profits of their more honest neighbours.

True, rejoins Mr. King ; but the grinding traders with their long-extended hours would not gain much, for all decent people would stick to the early shops.

We would add, that if a man lost a few pounds by his humanity, he might reckon it so much bestowed on the comfort and improvement of his assistants ; and a philanthropist would no more ask them to abstain from fresh air, that he might gain a trifle, than to sleep on straw, that he might save the expense of feather-beds.

An objection, however, which Mr. King has omitted to mention, might be started in poor districts, where the shops chiefly depend on the custom of the working classes. The journeyman cannot buy his goods till his work is over, and if he is not at liberty till 6 or 7, the shops which supply him will be open till 10 or 11.

Among the poorest classes, even the wife is often occupied till the evening. This is a formidable difficulty, which we scarcely know how to get over, except by a return to the practice, (which one reads of in books on popular antiquities) of making Saturday a half holiday for the community in general. Now that utilitarianism has bereaved many schoolboys of this their hereditary right, it may seem Utopian to hope its revival for men ; yet stranger things have come to pass.

With this exception, the reform would be as practicable as it would be commendable.

It is a *vexata quæstio* whether chemists' shops could be closed on Sundays. Every friend to their physical

as well as moral welfare must wish it were possible; but Mr. King does not quite overcome the difficulties of the case, when he supposes that medicines are required on Sunday only in cases of sudden illness. A case of phthisis of twelve months' standing may demand a fresh prescription on a Sunday; and if chemists' shops were closed, the physician's patients would lose an advantage which the patient of the general practitioner would still enjoy. He thinks that in the rare case of medicine being wanted on Sunday, the chemist might be fetched home by a special messenger, as a physician is brought to a case of apoplexy. But he forgets that a physician has regular patients to visit on Sunday, as well as these alarming cases of sudden illness. Mr. King also proposes a *rota*, or alternate succession, of chemists who are to open their shops on ordinary days after half-past 6, and on Sundays, "if necessary." If nothing but medicine, moreover, was sold by them on Sunday, it would materially diminish the mass of business, and perhaps give entire rest to all but one assistant, where several are kept.

Some customers, we imagine, would object to change their shop, and shrink from taking the next offered by the *rota*, especially if driven to this expedient even on week-days at half-past 6; if confined to Sunday only, it might perhaps be borne.

If the chemists, however, from the peculiarity of their trade, afford less than an average hope of improvement, many other tradesmen are far above the middle level, and would find eight hours a day an ample time for keeping their shops open.

Mr. King supposes the objection made, that it is impossible to finish business at half-past 6, as a general rule; for in the season it is as much as can be done to finish at 9 or 10.

Suppose, for instance, a wedding suit is ordered in a hurry, what is to be done? Mr. King answers that wedding suits ought not to be ordered in a hurry, and that as a match is not made up in 36 hours, neither ought the clothes. Without giving Mr. King the pleadings of the guest invited to the wedding, and the tailor whom he patronizes, we would comprehend this and many other points of detail in one simple generalization. The question is one between the convenience of the customer, and the health of the trader or workman. This question, like most others, is settled by a compromise; but, at present, the adjustment is so extremely on the side of convenience that the point of compromise might be moved considerably to the side of health, to the manifest advantage of the community.

There are two objections to the reform, which it is hardly necessary to consider: 1. That young men would misapply the time bestowed on them. 2. That they may read in the shop, during the intervals of custom, "snatching a fearful joy."

As to No. 1, if worth anything, it is an argument against liberty in general.

No. 2 forgets that exercise is as essential as reading. In many shops, too, far from reading being allowed, it is the law, that during the intervals of business, the young men are to whisk about the goods, to give an air of employment, and dazzle the entrant customer.

Mr. King very judiciously exhorts tradesmen, who constitute part of the public to every trade but their own, to avoid buying as well as selling after a certain hour. To effect all this, combination is requisite, but unanimity in the most literal sense is not necessary; for a minority of shops remain open on Sunday, yet the great majority being closed, the community is benefited accordingly.

We cordially hope that the Association will succeed in the noble object of their labours; and that the industrious persons whose cause they advocate may obtain time for improvement of the mind, and the relaxation of the body. Perhaps a time may come when it will be seen that the hours of labour may be generally shortened, with advantage instead of loss to the community. The Greek epigrammatist thought six hours of daily toil sufficient.

Ἐξ ὥρας μοχλοῦς ἰκαίωται αἱ δὲ μετ' αὐτὰς
Γραμμασι δεικνύναι ΖΗΘΙ λέγοντι βροτοῖς.

Six hours unwearied to stern labour give,
While those that follow cry to mortals "live!"

FIRST FORMATION OF THE GRAAFIAN FOLLICLE.

BISCHOFF agrees with Henle in viewing the Graafian follicle in its early state, when it has for its wall a simple structureless membrane, as similar in nature to those vesicles which Henle and Goodsir find to be the elementary constituents of glandular structure.

This view of Henle does not coincide with the representation given by Valentin of the development of the ovaries and Graafian follicles. The latter he describes as being formed within blind tubes, which originally constitute the structure of the ovaries, as the seminiferous tubes the testicles, but which become obliterated by the increasing growth of the Graafian follicles. Bischoff, however, says he has never been able to discover any such structure in the ovary as that which Valentin describes, notwithstanding every possible attention in the examination of the embryos of man, the cow, sheep, sow, dog, rabbit, hare, and rat.

Henle's view is likewise not in agreement with what Martin Barry says on the subject. According to the latter, the first-formed part of the Graafian follicle, which he calls *ovisac*, is developed around the already existing germinal vesicle.

Though Valentin differs from Henle and Bischoff in the account of the conditions under which the Graafian follicle is first developed, he appears to agree with them that the ovum is formed within the Graafian follicle, and not, as Barry states, the Graafian follicle around the rudiments of the ovum. *Brit. and For. Medical Review.*

FIRST FORMATION OF THE OVUM.

PERKINJE, the original discoverer of the germinal vesicle, conjectured that this might be the part of the ovum first formed. The observations of Baer and of Wagner on certain of the invertebrata, showed that as regards these animals such is the case; and as regards vertebrata, Dr. Martin Barry believed his observations warranted him in stating, that in the rabbit and pigeon at least, the germinal vesicle is the part of the ovum first formed.

The following is Bischoff's account of the first formation of the mammiferous ovum:—The fundamental part of the Graafian follicle being formed in the manner above described, contains a clear fluid, in which are suspended nuclei and granules, the latter quite similar to the subsequent yolk-granules. The size of the Graafian follicle at this period varies from 1-1000th to 1-333d of a Paris inch. On the inner surface of the *tunica propria* of the follicle, there is deposited a layer of endogenous cells as an epithelium. After this, there is found in the centre of the follicle a nucleated cell perfectly similar to the germinal vesicle, which, indeed, Bischoff holds it decidedly to be. Around this vesicle are then found deposited those granules similar to yolk-granules, and that in greater quantity the more advanced the development is. At the next stage, when he was able to satisfy himself of the precise state of matters, Bischoff found in the Graafian follicle the ovum with all its essential parts, viz. vitellary membrane (*zona*), yolk, germinal vesicle, and its spot. The smallest follicles in which such an ovum could be distinguished measured 1-100—1-20th of a Paris inch in diameter.

In the ova at this period, the vitellary membrane (*zona*) is very faint, and its external boundary not well defined. The yolk also is still clear. These parts, therefore, are difficult of being seen through the wall of the Graafian follicle, especially as it is no longer so transparent as formerly, in consequence of its *membrana propria* being now surrounded externally by a quantity of fibre-cells, from which is developed the cellular and vascular coat which subsequently forms the wall of the Graafian follicle. Hence Bischoff has not been able to perceive the formation of the vitellary membrane (*zona*). Everything, however, appears to him in favour of Valentin and Henle's opinion, that the yolk-granules are deposited around the germinal vesicle, and then become surrounded by the vitellary membrane (*zona*). Bischoff here repeats that in the formation of the ovum he has never seen, in addition to the vitellary membrane (*zona*), a trace of any other membrane to which the name

vitellary might be given, such as Valentin and Barry allege exists.

The earlier the stage of development, the larger is the ovum in proportion to the Graafian follicle. The ovum, indeed, is at first almost closely embraced by the Graafian follicle, as the ovarian ovum of the bird is by its capsule. The earlier, also, the stage of development, the larger is the germinal vesicle in proportion to the ovum.—*Ibid.*

MORTALITY OF THE METROPOLIS AND PRINCIPAL TOWNS IN ENGLAND.

By the quarterly tables of mortality made up to the 30th of September in the present year, we find that the number of deaths registered in the metropolis during the last year was 45,272, being less than in any one of the four preceding years. In the principal provincial towns, taking them together, the mortality was about 2,000 more than in 1841, but less than in any one of the three previous years. In the quarter ending the 30th of September, the number of deaths in the metropolis from all causes was 11,091, being about 70 more than the average number in the corresponding quarter for the five preceding years. Of those 2,706, the highest of any particular class of diseases, were from disease of the lungs and organs of respiration: but that number was 136 less than the average quarters of the five preceding years; the next highest class were epidemic, endemic, and contagious diseases, the deaths from which were 2,619—being about 180 more than the average quarters of the five preceding years. Diarrhœa and dysentery prevailed to rather an unusual extent, and appeared to have been equally prevalent in the country. In the provincial districts, scarlatina, measles, and enteritis, had also been prevalent. With respect to the temperature, the mean height of the barometer during the last summer was higher than in 1841 and 1842, or the mean height of the nine years from 1831 to 1840. The fall of rain was 5.662 inches, which is near the average; but it fell on only 23 days; whilst in the summers of 1841 and 1842, it was from 8 to 9 inches, and fell on from 47 to 50 days.—*Times*, Nov. 2.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, October 27, 1843.

R. B. Hole.—F. Smith.—E. Walker.—J. E. Partington.—R. W. Lammiman.—M. Burnup.—A. B. Andrews.—G. V. Birks.—J. C. Croft.—W. Sheppard.—J. N. Greensill.—B. Viret.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, October 26, 1843.

J. Green, Chapel en le Frith.—D. M. Aitken, London.—H. P. Freeman, London.—A. G. M. Moger, Bath.—W. H. Cane, Uxbridge.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending
Saturday, October 21, 1843.

Small Pox	8
Measles	30
Scarlatina	58
Hooping Cough	47

CLINICAL LECTURE

ON

A CASE OF PNEUMOTHORAX.

Delivered at St. Thomas's Hospital,

By DR. BARKER.

THE case which I take as the subject of my lecture this morning, is one which did not present any great difficulty to forming a correct diagnosis, and there was nothing remarkable either in its treatment or termination; but it is well worth your careful attention as a good illustration of the way in which diseases of the chest, the ordinary symptoms of which are, for the most part, easily recognized, may be modified and changed by adhesions of the pleuræ, the consequence of previous disease. It is also an example of the frequent absence of the usual signs of acute inflammatory disease, especially of the serous membranes, when the patient is much debilitated, or when the surface of the membrane has been changed by a former attack of inflammation. A full history of the case has not been preserved; but my notes of it are sufficient to enable me to lay before you its more important features, especially those relating to the two points just mentioned.

George Ivory, aged 49, formerly a sailor, but latterly working as a carpenter, was admitted into King's Ward on the 21st of March, 1843. No accurate account of the time when he was attacked, or of the nature of his first symptoms, could be obtained, either from himself or friends, except that he had been ill several days; and, it was also stated, that he had formerly been very intemperate, but had latterly, in consequence of his circumstances being much reduced, lived very low. At the time of admission he was labouring under the symptoms of a mild form of continued fever, such as are usually observed at the end of 12 or fourteen days.

The delirium, however, which was present, resembled that of delirium tremens much more than that which is usually seen in typhus. He had not slept for several nights.

The bowels not having been open for three or four days, an injection was administered, which acted freely; and he then became more rational and quiet; but he was still rather delirious, and there was no change in the nature of his delirium. He took a third of a grain of hydrochlorate of morphia in the evening, which, although it did not produce much sleep, caused him to pass a quiet and comfortable night. The next day, the pulse, tongue, and skin, and the muscular and nervous systems, all indicated an advanced stage of continued fever, without any extraordinary depression; and unaccompanied by signs of disease in the head, chest, or abdomen, with the exception of respiratory sounds, which will be noticed afterwards; and delirium, which, however, was less than on the previous day, though it retained the same character as at first. He was ordered to have wine, brandy, and porter, together with such diet, in the form of beef-tea, arrow-root, milk, &c. as he could take.

He passed a good night without having the morphia repeated; and, on the 23d, he was better in all respects. He liked the stimulants, and took a great quantity of nourishment. He improved rapidly in all respects until the 28th. When I saw him on the 29th, there was no apparent change for the worse; but I was informed he had had a long-continued rigor on the morning of the 28th, had been very hot during the whole afternoon, and had perspired freely during the night. The rigor occurred again on the morning of the 29th; but, when I saw him in the middle of the day, he appeared as well as usual; and, after a most careful examination, I could detect no sign of local disease, except in the chest, as I shall mention immediately.

A mixture, containing two grains of

quinine and a little sulphuric acid, was ordered to be taken three times a day.

After this day he had no rigors, perspired very little, and the improvement again progressed; but he did not regain muscular strength so rapidly as at first, and he complained of a constant slight cough. A blister was applied to the chest on the 31st, and was repeated on the 5th of April, giving good relief.

No minute record of this case having been kept, I can only speak in general terms respecting the physical signs of disease in the chest. At the time of his admission the whole chest was carefully examined, and no sign of disease could be detected, except slight sonorous and sibilant râles, here and there, such as might be expected in a man subject, as this patient was, to chronic bronchitis. The anterior and lateral parts of the chest, as far back as the stethoscope could be applied without making the man sit up, were examined at every visit, without any change in the character of the respiration being detected. On the 31st, when the cough became more troublesome, the whole chest was again carefully examined, when every part gave a clear sound on percussion, and no unnatural sound was detected, except the sonorous and sibilant râles, which were slightly increased. After this no very careful examination of the chest was made, except at the anterior part, which was examined daily, and one complete examination at my visit on the 5th of April, until the 8th, when my attention was arrested by the very feeble sound of the heart, and the absence of all impulse in the præcordial region; whilst, at every systole of the heart, a distinct splash, accompanied with a slight metallic ring, could be heard a little below, and about an inch and a half anterior to, the left mammæ—where it was most distinct—and about one inch in every direction from that spot.

A complete examination of the chest was immediately made. Over the whole of the right side the sounds heard on percussion and auscultation were quite healthy, except the râles already mentioned, which were slight. Over the anterior part of the left side, to a little below the mamma, and over the lateral part to a lower point, and as far back as half way between the sternum and spine, the resonance on percussion was good, the respiratory murmur was distinct, though not so loud as on the right side, and slight sonorous and sibilant râles could be heard. Over a space of not more than two square inches below and anterior to the left nipple, where the splashing sound made by the heart could be heard most distinctly, the resonance was much louder than natural, but no respiratory murmur could be heard there. At every other part of the left side percussion

elicited a dull heavy sound, and no respiratory murmur could be heard. Except the signs just enumerated, there were no symptoms of disease within the chest. The pulse was quiet, the respiration neither hurried nor laboured, the position in bed natural, and the cough much slighter than it had been a few days before.

I immediately called your attention to this case, as one of pneumothorax, in which a complete collapse of the lung was prevented by adhesions.

Of the existence of fluid and air in the left side of the chest there was conclusive proof in the splashing sound, and tinkling or metallic ring, caused by the movement of the heart: such sounds could only exist in a case where there was either air and fluid in the cavity of the pleura, or a large half empty excavation in the lung; and the whole history of the case was opposed to the latter supposition. It was, moreover, in the highest degree improbable that a large tuberculous cavity should exist in the lower part of one lung, whilst all the rest of that lung, and the opposite side, were free from tuberculous disease; which was certainly the case with this patient. On the other hand, the symptoms were consistent with the supposition that air and fluid existed in the left pleura, and that the left lung was partially kept in contact with the ribs, and prevented from collapsing completely, by adhesions. The only symptoms which I could not explain were, the permanence of the very clear resonance on percussion, at one particular spot, whatever might be the position of the patient; and the absence of any sign of the heart being pushed to the right side of the chest, when it was evidently not in its proper position on the left; since no impulse, and very little sound, could be perceived in the præcordial region; and there was clear resonance, and an entire absence of heart sounds or impulse, on the right side of the sternum. The first of these anomalies I supposed to be caused by some peculiarity in the adhesions; the second I could not account for.

The case was obviously one not admitting of any treatment save that already adopted—stimulants and nourishing diet. The patient continued perfectly easy and comfortable, making no complaint, except of muscular debility and slight cough. The pulse remained under 90, small and feeble; the respiration was not hurried nor uneasy; he lay on the back, a little inclined to the right side; the tongue was moist and clean; the bowels regular; appetite good; sleep natural.

Without any marked change he expired suddenly, on the morning of the 10th, while getting into bed.

A post-mortem examination, of the chest only, was made 48 hours after death.

The right lung was healthy, and there were no adhesions of the right pleura. The heart was pushed to the right side, so that not more than an inch of the apex was to the left of the sternum. There was air anterior to the apex, and the base was completely overlapped by the edge of the right lung, so as to render any sound or impulse, on the right of the sternum, during life, impossible. On the left side of the chest the lung was found adhering to the anterior and lateral parietes, except at the lower part, where, over the precordial region, there were no adhesions, the anterior part of the pericardium being at least an inch distant from the chest, and separated from it by air; the posterior part was immersed in fluid. At the side of the chest, the adhesions were continued down to the diaphragm, in such a manner that the air could not have changed its position, so as to rise to the upper part of the chest posteriorly, unless the man had had his feet much elevated, and then, after having been turned on his face, had been placed in the erect position. Thus the anomaly of the air in the cavity of the chest, not changing its place as the position of the man was changed, during life, was completely explained. The lower and the posterior parts of the chest were filled with serum, intimately mixed with a fine yellowish granular matter, like broken down fibrin. Although the adhesions did not affect the greater part of the posterior part of the left lung, there were two narrow bands of adhesion, stretching from the lower part of the upper lobe directly backwards, which, no doubt, greatly assisted in preventing the compression of the lung by the accumulating serum. The pleura itself was covered with a thin rough layer of fibrin, which, though closely adherent, could be scraped off with a scalpel. On examining the partially collapsed lung, to discover the cause of the pneumothorax, I found no disease in any part, except a small gangrenous spot, from which an eschar had evidently separated, at the posterior and lower part of the lower lobe; and this, no doubt, had been the cause of the recent attack of pleuritis, as well as of the entrance of air into the cavity of the pleura.

This is a singular case; but I have not called your attention to it so much on account of its singularity, as for the sake of the useful lessons, applicable to ordinary cases, which may be learned from it. One of these practical hints is sufficiently obvious—that adhesions may cause respiratory murmurs to be heard in parts where, in certain diseases, no respiration would be going on if there were no such adhesions. No general rules can be laid down upon this point, and it would be tedious to record every kind of deviation from the usual symptoms of disease

which has arisen from this cause. I shall content myself, therefore, by calling your attention to the fact, that partial adhesions, of greater or less extent, in different cases, may exist in every part of the pleuræ; and you may look for corresponding variations in the sounds, heard on percussion or auscultation, whenever pleuritic effusions of any kind occur in such cases.

But the absence of the ordinary symptoms of pneumothorax, as indicated by percussion and auscultation, in consequence of adhesions of the pleuræ, is not the only peculiarity in this case from which an important practical lesson may be learned. A great change took place in the chest of this man, without any alteration in his symptoms which could have led to the suspicion of such change. On the 31st of March the whole of both lungs were permeable to air, and there was no fluid in the pleuræ; eight days later there was so large a quantity of fluid, in the left pleura, that the lung was compressed to one-third of its natural size; and, during the same period, there had been an attack of pleurisy sufficiently acute to cover the whole pleura, where it was not adherent, with lymph. Nevertheless there had been no pain, no uneasiness, no acceleration of the circulation or respiration,—the respiration, indeed, had become more healthy,—no fever, and no unusual position of the patient in bed—in short, none of the prominent symptoms we should expect in such a case. How are we to account for this, and what are the cases in which we ought to look for disease of the chest without the ordinary signs? A solution of this question may, I think, be found in the following expression of Andral, when speaking of diseases of the pulmonary tissue. "Almost all the morbid states of these parts have one common and very important effect—that of diminishing the extent of surface on which the blood ought, when the parts are in a healthy state, to be presented to the air." But we may imagine two different results, as regards the arterialization of the blood, in the same state of the lung: a portion of lung being rendered unfit, more or less, for respiration, if the quantity of blood remains undiminished, there will be the ordinary train of symptoms; but if, the disease of the lung being the same, the quantity of blood be diminished in proportion to the diminution of serviceable lung, no such symptoms occur. This is proved by what we may observe every day. The difficulty of breathing and lividity of the countenance observed in pneumonia, in pleuritic effusions, and, most of all, in bronchitis, are removed by the abstraction of blood—or, in other words, by restoring the balance between the quantity of blood to be arterialized and the quantity of lung capable of performing that duty—long before any great change can be made in the state

of the lung itself. We constantly see similar phenomena in the course of many diseases : in emphysema of the lung ; in the altered condition of the mucous membrane arising from chronic bronchitis ; in partial solidification of the lung from any cause ; and, occasionally, in pleuritic effusions, the patient may, if, either from the effect of the disease or of remedies, the quantity of blood be reduced in proportion to the disease of the lung, be almost free from many of the symptoms of the existing disease ; there may be neither cough, nor pain, nor difficulty of breathing. But disturb the balance which has been gradually established—let the circulation be accelerated by exercise, by mental emotion, by stimulants, or by febrile excitement—or increase the quantity of blood by too full living, or want of attention to the secretions—or let the quantity of serviceable lung be farther diminished by an attack of bronchitis, however slight—and you will immediately see the latent disease proclaimed by all its ordinary symptoms. Such diseases of the lungs, as I have alluded to, are much more apt to remain latent, when, in addition to the diminution of blood to be arterialized, which takes place in the course of both acute and chronic affections of various kinds, we find the sensibility of the nervous system much blunted ; and, it is from these causes combined, that we so often find pneumonia gradually creeping on, until a considerable portion of one or both lungs is affected, in old, feeble, bedridden persons, or in those who are in an advanced stage of, or in the early convalescence from, typhus. I was once present at the post-mortem of a middle-aged woman, who had long been depressed by want and mental anxiety. She “had sunk gradually, without a symptom,” as I was told by the medical attendant, although she had been well taken care of for a month before her death. The whole of the right lung, except the anterior edges, was hepatized, and at least half the left lung was in the same state. Both the medical man who had seen her daily for some time, and the nurse who had been almost constantly in the room, assured me that no symptom or complaint had ever directed their attention to the state of the chest. The stethoscope had not been used.

The observations I have made on the possibility of chest diseases remaining latent, does not, of course, apply to those which are attended with much febrile excitement, or great secretion in the air passages ; but it is important to bear in mind that some of these diseases which are classed amongst the more severe pyrexia often exist—especially under the circumstances just specified—without any, or with very little, fever.

In addition to a great part of Ivory's left lung being compressed by pleuritic effusion,

without any apparent impediment to respiration, he had an attack of acute pleurisy after the 31st of March, without pain, fever, or any difficulty of breathing, which was accidentally discovered on the 8th of April. I have often observed attacks of acute inflammation of serous membranes without any of that pain which is so characteristic, fever, or disturbance of function, under two circumstances, which may exist separately or together—first, when all the powers of life are much depressed by previous disease ; and, secondly, when the membrane has been altered by a previous attack of inflammation. Now Ivory was debilitated by former habits of intemperance, by hardships immediately before his last illness, and by an attack of fever, from which he was just convalescent ; and the surface of the pleura had been changed by a former attack of inflammation, as was proved by extensive old adhesions. His was a case, therefore, most favourable for the existence of latent pleurisy. I have seen many similar cases of pleurisy ; and within the last year I have seen two cases of peritonitis, from perforating ulcers of the intestines, supervening upon a chronic form of the disease ; and one of pericarditis, in which the pericardium was scabrous, probably from a former attack ; all occurring in debilitated persons, and all wanting the symptoms which usually attract our attention in such cases.

From these observations you will perceive that the case, which has now been considered, is a good illustration of the two points mentioned in the commencement of my lecture—first, that partial adhesions of the pleura may change, or greatly obscure, the symptoms of pleuritic effusions of all kinds, by causing respiratory sounds to be heard where they do not, in such diseases, ordinarily exist ; and, secondly, that many acute diseases, especially of the organs of respiration, may remain latent, though not beyond our powers of discovery, provided due diligence be used. From this you may learn that cases occur in which a careless and insufficient use of the stethoscope not only fails to discover the truth, but leads into error ; and also that, in many diseases where there is great debility, especially in fever, a constant and complete examination of the chest is necessary, even if there be none of the ordinary signs of pulmonary disease.

I have dated the commencement of the pleuritic effusion between the 31st of March and the 8th of April ; I feel no doubt, however, that the examination at my visit on the 5th was sufficiently careful to assure me that no pleuritis existed on that day.

CLINICAL REPORTS OF CASES,

TREATED AT THE GLASGOW EYE
INFIRMARY.

BY WILLIAM MACKENZIE, M.D.

Complete ectropium of left upper eyelid from cicatrization, consequent to an abscess—Cure by a blepharoplastic operation.

CASE.—No. 13190, Aug. 10, 1843.—Maria Connell, aged 14. When about 16 months old, received an injury by a gate falling upon her, in consequence of which an abscess formed in left upper eyelid, which, bursting through the skin, discharged matter for many months. This was followed by ectropium, to such an extent, that, when the eyes are open, a large portion of the conjunctiva of left eye is exposed, and the cilia tilted up so as to be in contact with the eyebrow.

FIG. 1.

The ectropium is increased when she attempts to close the eye. There is a very great deficiency of skin in the everted eyelid, and it feels as if bound by a band to the inner surface of the orbit. Upper part of left cornea hazy, and vision of that eye so imperfect that she with difficulty distinguishes one finger from another with it. Keeps the eye constantly covered, to hide the deformity.

The everted eyelid was divided transversely in the seat of the cicatrice, and the edges dissected so as to open up the wound, A B, fig. 2, and allow the lid to resume its natural situation. A piece of pasteboard was laid on the temple, and the flap, B C, was insulated with the scalpel, of the exact size and shape of the piece of pasteboard. The anterior edge of the flap was continued into the wound of the eyelid. The flap was dissected off, except at its basis, B, turned

FIG. 2.

round into the wound of the eyelid, B A, and connected with its edges by stitches. The edges of the wound in the temple were brought together by three stitches. A considerable degree of ectropium still remained. Both eyes were covered with spread pledgets, and a double-headed roller applied from the hind-head forwards.

13th.—The external dressings were removed. There is little or no swelling about the parts that were cut, and she makes no complaint of pain. The lid appears more in its natural place than it did immediately after the operation, owing, probably, to the support of the dressings and bandage. No stool since the operation.

Cap. Pil. Colocynth, ii. q. n.

14th.—Three of the stitches removed.

Rep. Pil. Colocynth.

15th.—Six more of the stitches removed, being all those which served to keep the flap in its new situation. Two stitches remain in the wound in the temple, which appears quite united. Has considerable motion in the new eyelid. Stripes of court plaster were applied in place of the stitches along the lid, and another stripe across both upper and lower lids. Compresses and a roller were applied over both eyes.

Rep. Pil. Colocynth.

16th.—All the stitches removed, as well as a ligature which was applied on one of the branches of the temporal artery. Two stripes of court plaster applied across the left eyelids, and both eyes covered with a compress and roller.

21st.—All the dressings omitted.

Utat. velamine præ oculis ambobus.

24th.—On closing the eyes, without mak-

ing any particular effort to do so, the left lids do not come together, but leave an interstice between their edges of about one-tenth of an inch in breadth; but on making an effort to close the eyes, the edges of the left lids come together perfectly. On looking straight forwards, the left lids are open almost exactly to the same extent as those of the right eye, but the eyeball is a very little directed more downwards than the right. This seems the effect of having long retained the eye in that position previous to the operation. The cicatrice by which the upper edge of the flap is united to the eyelid forms a depression exactly in the situation of the natural sulcus, formed by the action of the levator muscle. The lower edge of the flap is united without any evident cicatrice. The line by which the edges of the wound in the temple is united is scarcely distinguishable; and it would be impossible to discover by mere inspection that at B any turn or change of place had been given to the flap. Not the slightest eversion remains.

REMARKS.—From the very great deficiency of integument in the everted eyelid, there could be no hesitation as to the choice of an operation in this case. It was evident that a transplantation of skin only could remedy the deformity. Suppose that Professor Chelius's method had been had recourse to, and an incision made through the skin of the eyelid, parallel and close to its edge, it might have perhaps been possible to have drawn down the tarsus into its natural place. After this, two or more loops of thread being passed through the skin of the eyelid near its edge, and fastened by plasters to the cheek, to keep the edges of the wound apart, till it granulated and cicatrized, months would have elapsed ere this could have been accomplished; during the whole of which time both eyes would have required to have been covered with pladgets, and a double-headed roller. Even after cicatrization was accomplished, the granulations would have been apt to be absorbed, and the eversion to return. After an incision nearly similar to that recommended by Chelius, Dzondi dressed the wound with resinous ointment mixed with cantharides, to insure a sufficiently copious process of granulation, before cicatrization should commence. He then applied lunar caustic, in order to heal the wound quickly, a practice against which Chelius warns us, as exceedingly likely to cause abortion of the granulations, and thus to defeat the object of the treatment. The methods of Dzondi and Chelius are much more tedious, painful, and uncertain, than the blepharoplastic operation.

It does not answer to trust to the eye, in estimating the size of the flap which is to be insulated and detached. It must be measured

by the wound, and the measure transferred to the piece of pasteboard, which is used to guide the scalpel. Owing to the contraction which the skin suffers both in breadth and length as soon as it is raised from its natural place, the flap requires to be considerably broader and longer than the wound into which it is to be received. Fricke says it should be one line broader and longer, but this would not be sufficient. At the same time, by applying numerous stitches as close as possible to the edges of the wound and of the flap, the latter may be extended considerably after it is adjusted to its new situation, and by employing pretty thick compresses and a double-headed roller it may be prevented from shrinking so much as it would otherwise do.

Connell's case was a simple one, and exactly adapted for the blepharoplastic mode of cure. The difficult cases are those in which the tarsus is adherent to the orbit, and even drawn considerably within that cavity, in consequence of caries. The detaching of the eyelid, so as to effect the necessary replacement of it in its natural position, before cutting the flap, is, under such circumstances, no easy matter.

When a blepharoplastic operation is determined on, the thickened conjunctiva should be left untouched, and no part of the skin, neither sound, nor hardened and contracted by previous cicatrization, nor any portion of the cellular substance, should, in general, be removed. The transplantation should first of all be accomplished; and when the incisions are healed, it will rarely be found necessary to interfere with the conjunctiva, or to shorten the lid transversely by the extirpation of any part of it.

The wound resulting from the raising of the flap should be closed by bringing its edges together, and healed, if possible, by the first intention.

CONTRIBUTIONS TO ANATOMY AND PHYSIOLOGY.

By ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 145.]

Supplementary Observations to the preceding Memoir: describing more minutely the Anatomical Preparations illustrating the Anatomy of the Cervical Ribs.

To avoid overloading the text with minute anatomical details, I have thought it best to throw into the form

of a supplement a number of anatomical facts connected with the series of preparations, of most of which I have given figures. These details may be of use to some future anatomist who purposes completing the history of the cervical ribs in man. The reader will do well to have the figures before him whilst perusing this supplement.

Figs. 2 and 3.—A figure of an anatomical preparation precisely similar to this is given in Sandifort's great work in the Museum of Leyden. He describes it as "the first rib with a double head." Sandifort's work was published in 1792, or thereabouts, thus showing that the philosophy of M. Hainauld had not penetrated into Holland. M. Hainauld wrote in 1740, and fifty years thereafter we find Sandifort totally ignorant seemingly of what he was describing.

The cervical rib is not quite so strong in the head, neck, and tubercle, as the first true or thoracic rib: still it is very fully developed, and the head and tubercle must have rested on distinct articular facets on the body and transverse process of the seventh cervical vertebra.

The two ribs unite about half an inch beyond the tubercle, and continue united throughout: the cervical rib extends no further than the process of insertion of the scalenus, which it seems to form. It is quite possible that the sternal end of the rib may occasionally be developed, and not the vertebral end. These bones are well ossified, quite adult, and firm; the head of the cervical rib must have rested on the middle of the body of the last cervical vertebra and that of the first true rib, between the seventh cervical and first dorsal: this fact I have now observed several times, and it establishes a curious analogy between this cervical rib as to its articulation with the column and the false ribs, the eleventh and twelfth, shewing resemblances between the two extremes of the dorsal part of the column and the adjoining regions.

Fig. 14.—In this figure I have not thought it necessary to give more than the last cervical vertebra, the first true rib, and four or five of the uppermost dorsal vertebrae; but in the preparation all the cervical vertebrae are present; it completely settles the question against Meckel's theory of the formation of the ribs, and is valuable in many

other respects, as it connects Hainauld's views, filling up the gap in his observations. I beg leave to refer the reader for a very full description to the body of the memoir.

Figures 15, 16, and 17.—The preparation from which these figures have been taken has been very fully described in the text; there are present the 5th, 6th, and 7th cervical vertebrae, and the 1st, 2d, 3d, and 4th dorsal. The texture of all the bones throughout is firm and well developed. The resemblance which the 7th cervical vertebra has on the right side to the dorsal is most remarkable, and it deceived many good anatomists; whilst in the left half it is quite a cervical vertebra. Notwithstanding this so near approach, the vertebra even on the right side may be distinguished from the dorsal: 1st. The transverse process, although it has a distinct articular facet, is not on the same plane as those of the dorsal, holding an intermediate position between the sixth cervical and first dorsal. 2d. Between the neck of the rib posteriorly and the transverse process (which here of course has only one root) the space left assumes a rounded form, differing from the form of the corresponding spaces lower down, and more resembling the normal vertebral foramen, if the process had had the anterior root, which, however, is wanting. 3d. The body of the vertebra presents on each side upon its *upper surface* a well marked ascending process, characteristic of the cervical, and wanting in the dorsal vertebrae. *This process* is present on both sides; the *first dorsal* vertebra shews a little of it on the left side. 4th. On the left side there is merely a transverse process formed, as usual of two roots, and a distinct foramen between them: no vestige of a cervical rib is visible. It is worth remarking that the transverse process of the seventh *follows* always a direction peculiar to itself, intermediate of the one above, and of that following. The preparation is from the adult; the osseous texture is firm and quite healthy. Lastly, there is a slight projection upon the inner margin of the first true rib, although the scalenus was not attached to it. There was of course an additional pair of intercostal muscles, though on one side only.

Fig. 18.—It is curious to observe in this preparation how nearly symme-

trical the seventh cervical vertebra is here in parts which are anormal. The *two* supernumerary ribs, for there were two, resembled each other strictly; on each side of the body of the vertebra about its middle there is an articular facet; each transverse process has also an articular surface, and neither has a vestige of the *anterior* root of the transverse process. But for the *ascending processes* of the body, it might easily be mistaken for a dorsal vertebra.

Fig. 19. — The preparation from which this was taken is composed of all the cervical vertebrae, and the 1st, 2d, and 3d dorsal. The spine has been fully developed, and is adult. The seventh cervical alone presents peculiarities worth noticing here. The anormal structures are again in this preparation tolerably symmetrical. On the right side, the anterior root of the transverse process, and the rudimentary rib, have run together, both having been very imperfectly developed at first. A foramen of the usual form is thus left passing through the base of the transverse process so formed; but external to this we find *another* foramen, the rudimentary rib, having seemingly acquired strength; the rib, bent, runs outwards and forwards for about an inch, and gradually ceases in a sharp point, turned forwards and inwards. On the left side it is much the same, but instead of *two foramina* there is but one narrow elongated. The first dorsal carries distinct ascending processes on its body.

Fig. 13. — This preparation confirms many of the preceding statements, and offers also some new facts. Although the right cervical rib is much shorter than the left, what there is of it is quite as well developed as that of the opposite side. The vertebral artery may be seen entering the foramen of the sixth vertebra on the right and left sides: the whole of the bones are large and strong, and quite adult. As usual the supernumerary ribs are carried solely by distinct facets upon the body and processes of the seventh cervical vertebra; the true or first thoracic rib rests on two vertebrae, and the intermediate fibro-cartilage.

—
*On the Cervical Vertebra of the Aï,
(Three-toed Sloth: B. Trid., L.)*

The fifth volume of M. de Blainville's splendid work on Comparative

Osteography contains a dissertation on a point in the history of the cervical vertebrae and cervical ribs of mammals intimately connected with the preceding observations. The aï or three-toed sloth is well known to present an anomaly in the number of its cervical vertebrae; and as M. de Blainville's work is scarce in Britain, I have thought it might be interesting to those who take an interest in the philosophic history of the human skeleton, to have this opportunity of comparing his remarks with mine, drawn as they are from human structure only. The following is a translation of M. de Blainville's note:—

"I have already said, at page 22, that I do not adopt the opinion of Bell, who thinks that those vertebrae (eighth and ninth cervical), which exceed the seventh in the neck of the aï, ought to be considered as thoracic or dorsal. I purpose in this note assigning my reasons for holding an opposite opinion, dwelling for an instant also on the fact of the number and nature of these vertebrae, which in the three-toed sloth exceed by one or two the number seven, the number found constantly not merely in man, but in all the mammalia as yet described, as well as in the unan or two-toed sloth; in all the species, however, they may approach or be removed from the human species; whatever, moreover, be the length of the neck, whether, as in the giraffe, the neck be as long as the body, or from its extreme shortness it seems wanting, as in the lamentins and dolphins.

"Although the generalization of the fact that in all the mammalia there are but seven cervical vertebrae, be in the most positive manner ascribed to Daubenton by Cuvier, (and that he had observed the fact seems probable from the circumstance of his having counted and minutely measured most parts of the skeletons of many mammals), I yet find that his generalization was first distinctly stated by Blumenbach, in his Descriptive History of the Bones, a work published in German, at Göttingen in 1786: his expressions are, "it appears that the presence of seven cervical vertebrae only ought to be viewed as a general and constant rule in all the mammalia, at least in those with four feet;" and Vieq d'Azyr, in his *Traité d'Anatomie*, t. i, p. 30, published the same year, states the

same generalization still more distinctly, without alluding in the slightest manner to Daubenton, although constantly in the practice of doing so. In fact, I do not believe that Daubenton mentioned this fact in his lectures at the normal school.

"In respect to the exception to the law which we find in the *ai*, it may be observed that it might have been suspected, from a coarse drawing of this sloth given by Pison, or rather by Margrave, in his *Medie. Utriusque Indiae*, p. 322; but this did not happen. It is remarkable that Daubenton, in his comparative description of the skeleton of the *unan* and *ai*, in the "*Histoire Naturelle de Buffon*," has detailed very exactly the number of dorsal, lumbar, sacral, and coccygeal vertebræ of these animals, and, against his usual practice, has taken no notice whatever of the cervical vertebræ, although, notwithstanding that the skeletons were those of young animals, they were just as easy to count as the others. Thus, in 1765, the year of Daubenton's publication, the anomaly had not been pointed out: and as, in 1786, Vieq d'Azyr says that all mammals have seven cervical vertebræ, the exception had not been pointed out in the interval. Neither Riche nor Sylvestre noticed the fact in their analyses of the Transactions of the Philomatic Society made between the years 1799 and 1800; and still, although in the "*Tableau Methodique des Animaux*" published by M. Cuvier at the commencement of 1798, we find the unqualified assertion of Vie d'Azyr, that the mammals have without exception but seven cervical vertebræ, the "*Leçons d'Anatomie Comparée*, published two years afterwards, that is, in 1800, distinctly takes notice of the exception in the following terms, t. i. p. 154:—"Excepte dans le paresseux à trois doigts, qui en a neuf."

It would seem, then, that the anomaly had been observed in this short interval, and published, no doubt by Wiedemann, in his first fasciculus of vol. I of his *Archives de Zoologie et de Zootomie*; since M. Cuvier, in the first edition of his "*Memoir sur l'Osteologie des Paresseux*," says, "that since the time of Daubenton, M. Wiedemann, professor at Brunswick, has made researches on this subject, and has published a detailed description of the cranium of the *ai* (*Archiv. de Zool. et*

Zootom. t. i. fasc. i. p. 46, with figures, plates i. and ii.); also another more abridged description of the young skeleton (*ibid. p. 132*), without figures, and some additional remarks made in the Parisian museum, as well on the skeleton of the adult *ai*, as on the cranium of the *unan*, *ibid. t. iii. fasc. i. p. 57*;" and in the second memoir in 1823, M. Cuvier adds, whilst speaking of the peculiarity of nine cervical vertebræ in the *ai* (*tom. iv. p. 82*); that "M. Wiedemann had made the same observation independent of a knowledge of M. Cuvier's discovery."

M. Cuvier's discovery was in fact developed in the first edition of the memoir just cited, and which was published in 1804; but still it is reasonable to believe that although he had not published it, M. G. Cuvier had made the discovery prior to Wiedemann, inasmuch as he says, in this very memoir, that he had mentioned the fact some years before to Daubenton. Now Daubenton died in 1800, after the first sitting of the conservative senate, in which he had been enrolled by Napoleon Bonaparte, and "some years before," would indicate at least 1798. In fact, M. Cuvier, in his second edition of his memoir, repeats what he had in the first, viz. that he hastened to publish the fact in the *Bulletin des Sciences* of the Philomatic Society. Unfortunately this assertion rests on no express quotation, and this no doubt has been the cause of its having escaped the observation of those who have inquired into this point of natural history; but it nevertheless actually exists in the "*Bulletin par la Société Philomatique*," about 1798, in these terms: "Citizen Cuvier here made mention cursorily of an interesting discovery he had made, that the *ai*, *B. Tridactyl.*, *L.* has uniformly nine cervical vertebræ; to which he added, that this is the first exception to the law laid down by C. Daubenton, that all viviparous quadrupeds have neither more nor less than seven cervical vertebræ."

In his memoir of the osteology of the sloth, M. G. Cuvier enters into more details explanatory of the circumstances which led to the discovery. His assistant, the elder M. Rousseau, having been directed by him to set up a complete skeleton, but of detached or separate bones which M. Richard had had the kindness to lend him, and com-

mening as is always the case by endeavouring to adjust and arrange the different vertebræ by regions, found that after having arranged the coccygeal, sacral, lumbar, and dorsal, there still remained nine, which he was obliged to consider as cervical, M. Richard having most certainly prepared only a single skeleton. M. Cuvier having been informed of this circumstance, which after all might prove merely an individual variety or anomaly, endeavoured immediately to set the question at rest by causing to be prepared under his inspection the skeleton of a young specimen preserved in spirits of wine, and by a more attentive examination of the individual specimen described by Daubenton. Now in both he found precisely the same number of vertebræ. Now this observation of M. Cuvier was published in the Bulletin of the Philomatic Society towards the middle of 1798, whilst Wiedemann published only in 1800. It is surprising therefore, that the latter, who had examined the Parisian museum, makes no mention of Cuvier's discovery, actually announced two years previously.

However this may be respecting the discovery of a fact which could not possibly have escaped notice from the period that the separate bones of a carefully prepared skeleton were about to be articulated, the subject was viewed perhaps for the first time scientifically by Mr. Bell, in a dissertation read by him to the Zoological Society of London, and published, with figures, in their Transactions. Dr. Harlan had, however, previously remarked, that the ninth cervical vertebra supported at the extremity of its transverse process an osseous rudiment of a rib, to which it is joined by a cartilage. To this Mr. Bell added, that the eighth cervical vertebra also carries, at the extremity of its transverse process, an osseous element evidently diarthrodial, that is to say, separated from the vertebra by a solution of continuity with an articular facet encrusted slightly with cartilage, and a synovial membrane partaking of slight motion, notwithstanding the density of the periosteal system; and on this Mr. Bell has advanced the opinion, that these moveable processes ought to be regarded as rudimentary ribs. Hence he thinks that these pretended cervical vertebræ ought

to be considered as dorsal or thoracic, and that thus the generalization of Daubenton (Blumenbach?) would suffer no exception.

There can be no doubt of the correctness of Dr. Harlan's discovery or observation, viz. that epiphysis is for a fleeting period articulated to the extremity of the transverse process of the eighth and ninth cervical vertebræ of the ai; it may, if examined with care, be seen in the skeleton of the adult; but it appears that an anchylosis, or bony union, takes place very early, and in three specimens I have examined the eighth cervical vertebra carried no such process, whilst those found on the ninth were not only much shorter than those seen by Bell, but were perfectly regular and symmetrical on each side; and hence it would appear that there was something anomalous or irregular in his specimen. However this may be, this is not the important question, which rather is, are these processes rudimentary ribs or not? And are the vertebræ carrying them to be viewed as cervical or dorsal? And have the sloths only seven cervical vertebræ, like all other mammals? Now this we shall hardly admit.

Dr. Harlan read his Observations on the Anatomy of the Sloth Ai, to the Academy of Natural Science in Philadelphia, several months before their publication in the Monthly Journal of Geology and Natural History. He seems to have had chiefly in view to disprove the theories of Buffon, and to prove the organization of the sloth to be perfectly in harmony with its providential destination*; a thesis afterwards adopted by M. Buckland, and defended in a special dissertation†, republishing the results in his "Theology of Mineralogy and of Geology", vol. i. p. 141. But, in addition, Dr. Harlan, in his "Medical and Physical Researches," Jan. 1835, touched the question we now consider, in a note added to the reprint of his original memoir. In this note he says that several anatomists having viewed these processes articulated with the two last cervical vertebræ of the sloth as ribs, he entertains, however, a different

* We venture to assert, that no other animal is so perfectly adapted by its peculiar organization for such a mode of life.—Harlan.

† On the Adaptation of the Structure of the Sloths to their peculiar mode of life.—Linn. Soc. Trans. 1833, vol. xviii. 1st part, p. 17.

opinion, because these processes are mere rudiments, and that the vertebræ themselves are complete—reasons which unquestionably are not at all conclusive, but which, notwithstanding, may be strengthened.

First, I do not see how these processes can be compared with, or considered as, rudimentary ribs: in fact, were we to compare them with the anterior asternal ribs in birds and in certain reptiles, we should find the comparison inappropriate, since they are neither bifurcated at the root, nor articulated with the body of the vertebra. On the other hand, were an attempt made to compare them with certain asternal ribs in the cetacea, the mode of articulation is an obstacle to the correctness of the comparison. And, moreover, these asternal ribs in the cetacea are always fully connected with two intercostal muscles, whilst the articular processes of the last cervical vertebræ in the *aï*, like the corresponding transverse process, give attachment merely to the termination of the scaleni muscles, as in all other mammals.

But the fact which most deserves attention is, that these vertebræ have the most essential, the most distinctive character of the two last cervical vertebræ—that even which enables us to recognise them in reptiles the most ophidian in their character: the eighth has, in fact, at the base of its transverse process, a foramen for the passage of the vertebral artery and great sympathetic, and besides, this process is divided into two lobes, an inferior, larger and broader, a superior, narrower but enlarged, as we find takes place in the corresponding vertebra (sixth) in other mammals, in some of which, unless I am deceived, I have observed, since my attention was more particularly directed to this point, there exists a sort of distinct epiphysis on this same vertebra. Now the ninth, that is to say, the last cervical, is equally distinguished as its corresponding bone (the seventh) in other mammals, by the absence of the foramen at the base of this same process, as well as by its form, which is long and narrow, so that this consideration alone is sufficient to demonstrate that these vertebræ, being evidently the bones analogous to the two last cervical (6th and 7th of other mammals) cannot be considered as thoracic, excluding them

thus from the cervical region; and that the supernumerary or additional cervical vertebræ necessarily belong to, and ought to be placed amongst, those I have called “intermediate cervical,” in my *Osteographie*.

An evident proof of the correctness of this view is found in the skeleton of the *aï* brought from Brazil by MM. Quoy and Guimard; in it there are but eight cervical vertebræ, and yet the two last are absolutely like the two last of those specimens which have nine. The diminution, then, in the total number is connected with, or falls on the intermediate ones, which in this case are in fact but four.

The same reasoning applies strictly to the man, in which there have never been found more than the normal number of seven. The two first, like the two last, have always their distinctive characters, and in it, as in all the other mammals, there are but three intermediate cervical vertebræ; and I may, by the way, venture to add, that when in certain animals there is an appearance as if there were but six cervical vertebræ, it will be found that the absent vertebra is an intermediate one; but there always remain traces, either in the body, the process-bearing arch having disappeared, or in the arch, the body having disappeared. Of the correctness of this view I have satisfied myself by an inspection of a carefully prepared skeleton of the dugong, belonging to the museum at Leyden, and in which the osseous arch (of one of the intermediate cervical vertebræ, it is presumed, K.) exists without the body; and this explains the condition of our skeletons of the lamantin, in which there exist only six cervical vertebræ, because in preparing by boiling, and articulating these skeletons, the rudimentary portions were detached and lost.”

In conclusion, then, I venture to suggest, that if we are to support the theory, that the eighth and ninth vertebræ of the three-toed sloth (counting from the atlas) are not cervical, but dorsal vertebræ, in consequence of their carrying rudimentary ribs, supposing the processes they do carry to be rudimentary ribs, then the nomenclature of the human osteology must be altered, and man removed from the list of mammals in whom the number of the cervical vertebræ is normal: but I feel

disposed to give a preference to the theory of M. de Blainville, which, by arranging the cervical vertebrae into three or more groups, admits of an increase or decrease in their number, without the violation of any other well-established philosophic theory.

MR. LEE

ON

BELGIAN MEDICAL INSTITUTIONS.

[Continued from p. 148.]

Colony of Insane at Gheel.

WE now come, continues Dr. Moreau, to the consideration of the treatment. The therapeutical part of mental diseases, which, in some respects, is analogous with that of all other diseases, requires besides, as an essential condition of success, a combination of hygienic circumstances, for which the colony is admirably adapted, and of which science has proved the necessity.

And, in the first place, as far as regards isolation. Should not this be the first step in the treatment of mental diseases? To isolate an insane patient is to completely break the habits amidst which his alienation has arisen; it is to separate him from the localities, the things, the persons, which are not dissociated from the disorder of his faculties: it is to destroy forcibly the ordinary association of his ideas, and to give them a new direction: it is to alter the vicious tendency of his affections: in a word, to create for him an entirely new moral existence. At Gheel, all these conditions are fulfilled. The place in which the patient lives, the individuals with whom he has daily relations, the labour, the mental diversion, are all new to him. He is not separated from all society, and he cannot fail to find, in that of which he has become a member, impressions capable of producing the most beneficial change in his morbid ideas.

All the insane at Gheel, men and women, unless prevented by some physical cause, must engage in manual occupation. That of working in the country is chiefly preferred, and it is particularly suited to the insane, inasmuch as the muscles are thereby exercised; it requires but little attention, no intellectual effort, and is performed in the fields in the open air. Pencil

required, for the insane, varied bodily exercise, a spacious locality planted with trees, measures of enjoyment, and the tranquillity of country habits. In the Hospice of Bicetre, I can every day perceive the beneficial influence which field-labour exercises upon the health of our patients. By creating the farm of St. Ann's, in which more than sixty patients are occupied in different kinds of work, M. Ferrus rendered a true service to humanity and to science.

The labours with which the patients at Gheel are occupied, the simple and frugal fare, the salubrious air of the country, contribute to their physical well-being. It is impossible not to be struck with the healthy aspect and fine condition of those met with in the streets, and in the country. They attain, in general, an advanced age. There are, at the present time, in the colony, some individuals between 80 and 90 years of age.

It must be admitted that there is much to be desired as regards the medical service. The colony is divided into four sections, confided to the same number of medical men, who reside in the village, and also undertake private practice. Their annual salary is but 200 francs. With so inadequate a compensation, it is scarcely to be expected that they can attend properly to the patients, and that they would not sacrifice their interests for the advantages of a much more lucrative practice.

The patients are, on their arrival, inscribed upon a register. After minute examination of the causes which have produced the disease, its duration, the treatment previously adopted, and all which relates to the new-comer, the physician is required to decide upon the curability or incurability of the patient, to fix the class, and place him in the position most conformable to the treatment, according to the nature of the predominating ideas.

This register is a rich collection of cases, of which, at the end of each year, a statistical account is rendered, and which, as regards the administration of the colony, and especially for science, is a precious document.

At the end of each year a general and medical report is made upon the state of the colony. The mode of treatment pursued at Gheel, is, with some slight differences, the same in

the four districts. It is that which Pinel and Esquirol have transmitted to us, and which is employed in all the insane establishments of Europe: viz. a pure medical eclectism, tending to combat the functional disorders which precede or accompany the intellectual disturbance. General and partial baths, the general and local abstraction of blood, purgatives, excitories, &c. form the basis of this medication. Affusions of cold water are likewise frequently employed. The douche, or a strong column of water falling upon the head, is unknown at Gheel. As a plain therapeutical means, it may very well be superseded by cold water applications or affusions—for the object is solely to produce upon the surface an impression of cold of a greater or less duration, to allay, by means of this impression, the inflammatory excitement, the occurrence of which in the brain is admitted.

A restricted diet may be advantageously made to supersede the douche. Its action is continuous, each hour that it is prolonged renders it more unendurable to the patient, especially as they have generally good appetites. Besides, by diminishing the physical forces it gradually weakens the moral energy, and in the end overcomes the most obstinate will.

Sedatives are likewise an excellent means of calming the habitual agitation of maniacs, and the temporary exaltation of monomaniacs (opium, stramonium, belladonna, hyoscyamus, aconite, &c.) The employment of those agents ought to be graduated in such a manner that, beginning with a very low dose, one may arrive at very large doses varying according to the nature of the patient's delirium, constitution, or idiosyncrasy.

From what has been said, it seems to me that by giving up the douche we should not be deprived of all means of repressing the exaltation of maniacs. The douche should therefore be proscribed, because it is painful, and is equivalent to an actual torture for some patients; because it fails in most of the cases in which it is administered, or rather inflicted; because as regards the two-fold point of view as a therapeutical and repressive means, it may be advantageously superseded; and likewise, for a reason to which it is neces-

sary to direct the attention in a special manner.

Insanity is the expression of a lesion of the nervous system, just as dyspnœa, palpitations, diarrhœa, are the expression of an affection of the respiratory organs, the heart, and the intestines: in a *philosophical* as well as in a medical point of view it is this, and nothing more. We must, however, admit that disorder of the intellect has the sad privilege over other functions of the economy, that of humiliating in their own eyes, as well as in the eyes of others, those who have the misfortune to be afflicted with it. We may conceive this idea of degradation, the moral debasement, the feeling of shame which the disorder of our highest faculties carries along with it. If this be the case, is it not the duty of the physician to calm as much as possible so painful a feeling? which, it is not sufficiently considered, is always aggravated, and is rendered more poignant and durable by the douche. Hence the excessive repugnance of patients to the douche, which begins by wounding their self-love, before making them suffer physically. When restored to society, patients remember with terror their having been douched, and this painful remembrance has often the effect of causing their relapse, or at least of powerfully contributing to it.

Let us return from this digression, to our colony. The following is the result of the treatment, as far as the cures are concerned, for the year 1840. On a total of 678 patients (353 men, 325 women) 40 (15 men, 25 women) were cured.

This number, so small with reference to the numerical quantity, is enormous as regards the *quality*, if I may so express myself, of the patients. For it must not be forgotten, that up to this day, with very few, if any exceptions, there have only been sent to Gheel insane persons who had previously been subjected to a treatment more or less prolonged; either in hospitals, or in their families, and had been deemed beyond the resources of art, and declared *incurable*. I am well aware that in mental medicine the prognosis is far from being infallible; but when a disease has existed for several months, or even years, and no treatment has succeeded in modifying

it, the prognosis is excessively unfavourable, even if it does not induce us to give up all hopes of recovery. Besides, the circumstance must not be overlooked, that, among the patients at Gheel, there is a considerable number of paralytics, epileptics, idiots, and imbeciles, who are all in a state of absolute incurability.

As I have already said, not more than two years have elapsed since the colony at Gheel has received a certain organization. No doubt with time (if this be allowed it), this organization will produce the fruits there is reason to expect from it, especially if the ameliorations be introduced of which experience may subsequently demonstrate the necessity.

SINGULAR CASE OF
MALFORMATION OF THE SEXUAL
ORGANS:

WITH ABSENCE OF THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty to transmit the following case, which I hope may be thought worthy of the attention of the profession.—I am, sir,

Your obedient servant,

E. SMITH, M.B.

71, Newhall Street, Birmingham,
Oct. 31, 1843.

On Sept. 13th, 1843, Mrs. Tinly, of Constitution Hill, was delivered of an infant having malformation of the sexual organs.

The perinæum was about $1\frac{1}{2}$ inches in length, having the precise characters of this organ in the male. At its anterior termination, and within five lines of the arch of the pubis, was a triangular-shaped opening, the apex being above and in front. Through this opening the urine was emitted; and along the canal terminating there, a small bent probe could be readily passed into the bladder. There could, consequently, be no doubt of its being the urethra.

In the central part of the perinæum, and about midway betwixt the urethral opening and the anus, was a slight elongated depression, having a faint blue tint shining through the skin.

In front of the arch of the pubis was

an elongated cylindrical body, having the precise appearance in position, form, and resistance, of a penis with the prepuce withdrawn. A substance similar to the glans penis was very evident, in the centre of which was an elongated fissure; no orifice of a urethra could, however, be detected in it. This penis was nearly one inch in length, and was curved downwards, being connected by the frenum preputii with the central line of the perinæum. This connection was immediately above the urethral opening, with which opening the fissure in the glans penis would be continuous, were it not for the transverse connecting point just mentioned.

On either side of this penis an oval flattened organ was placed, measuring twelve lines in length and eight lines in breadth. In form, position, colour, and stiated appearance of the integument, it nearly resembled the scrotum. It differed from that organ, however, by the two sides being separate and distinct. In the space betwixt these two sides of a scrotum the penis was situated.

Neither testes nor spermatic cord could be felt.

It now became difficult to ascertain whether these organs belonged to a male or a female child. The appearance was that of a male, since we had a body much resembling a penis, two organs analogous to the scrotum, and a urethral opening at the base of the penis. The non-perforated character of the penis did not militate against such conclusion, since such circumstance has been frequently found in individuals whose sex was certainly the male. The same remark also applies to the want of testes in the scrotum, inasmuch as many individuals have reached manhood before the testes had gained their proper position. The opening of the urethra, although abnormal, seemed to assist us in our conclusion, from its absolute position being so like that of the female, and from its relative position with regard to the base of the penis. We could not consider it to be female, because we had not the external fissure bounded by the external labia, nor the nymphæ, with any of the more internal of the external organs of generation. The scrotum-like bodies might be transformed labia, but their appearance did not admit of such

a conclusion; and the penis-like body might be an enlarged clitoris. The *tout-ensemble* was apparently that of a male child.

On the following day, Mr. Green and Mr. Thomas Chavasse, two highly talented surgeons, examined the child, and unhesitatingly pronounced it to be a male.

During the succeeding five or six weeks the infant was very restless and irritable, and became gradually emaciated. A considerable quantity of opaque mucus was discharged by the urethral passage. On October 30th it died, and a *post-mortem* examination was made the same day; when the following unexpected and unusual circumstances presented themselves:—

A normal and well-developed uterus, with its fallopian tubes and ovaries, were present. The canal leading from the external urethral opening was the vagina, about two lines in diameter, and perfectly cylindrical and patent. There was no urethra, but the neck of the bladder was inserted into the vagina: that this passage was the vagina, although not perfectly normal, is evident from the following circumstances. 1st, The direct course of the canal was to the uterus; the bladder being connected with it at an obtuse angle. 2d, The structure of its walls was that of the vagina, consisting of a mucous membrane, a dense layer of fibrous structure, and condensed cellular membrane. This structure was continued beyond the insertion of the bladder, even to the neck of the uterus. The anormal part of the urethra was its not terminating by a cylindrical opening, around which the fibres of the vaginal muscle might be located. The above-mentioned structure, also, did not proceed to the termination of the canal, but only the most internal twelve lines. The external eight lines were composed of mucous membrane and cellular structure only. But although the lower part of the canal bore some resemblance to the urethra, yet the circumstances above named will probably prove it to have been the vagina.

No testes nor spermatic cord could be discovered. The labia consisted of a portion of integument and cellular tissue folded upon itself; the two layers being very readily separated from each other.

This case appears to be interesting for three reasons. 1st, The great similarity of the external parts to the male organs of generation, which was infinitely greater than is usually observed in anormal conditions of the female organs. 2dly, The character of the canal, consisting of vagina with urethral termination—the termination also being anormal—and more especially from the direct insertion of the bladder into the vagina, causing the absence of the urethra. And, 3dly, It is illustrative of the observation made by Geoffry St. Hilaire, that the organs of both sexes were originally formed on the same plan. It also shows how purely speculative must be the opinion of medical men in such anormal cases.

ON THE
PART OF THE STOMACH WHICH
DIGESTS, AND THE SOURCES
OF HÆMOPTYSIS.

To the Editor of the Medical Gazette.

SIR,

It seems to me that an indifferent judge has been set to criticise my paper “on the Digestive Solution of the Œsophagus, and on the Distinct Properties of the two ends of the Stomach*.” I crave leave to appeal to you.

I attempt to shew that the left end of the stomach is the digesting organ, and that therefore this part alone is digested after death. The critic thinks that all the fluid gravitates to this part as the corpse lies, and so digestion is manifested here. He says, “We have seen much of morbid anatomy,” but he does not seem to know that the part of the stomach filled by gravitation (as above) is not the part most acted on by gastric juice. The perforations, &c., do not occur behind, but at the left side†. This, his evident want of obser-

* Vide Guy's Hospital Reports, 1842 and 1843; and No. 32 of the British and Foreign Medical Review.

† The same thing, as near as may be, occurs in all sorts of fishes who are not laid out very regularly on their backs to die. Hunter's words are, at the “usual place,” the “great extremity,” the “great end,” solution occurs. He says of the dog's stomach, “In the great end, the food will be but little altered (it is wiped away to the right as it is digested) towards the middle more, &c.” I have stated, the least altered part of a solid meal is the centre of the mass. Hunter, again, “There are few stomachs that do not shew, when examined after death, some of the

vation, may explain his objection to my statistical assurance that some "effects of digestion are as often discoverable as not" in London autopsies. Those who know how to look for the signs will not fail to find them.

With regard to the originality of my view the critic may do very well for hunting up forgotten expressions, but he is not honest in the following:—"The remainder of the paper is occupied with a series of observations in support of the *opinion* that the left half of the stomach is alone concerned in the production of the digestive fluid. After noticing the testimony of various authors to this *fact*," &c. now, as to facts, and opinions against me, I do quote various authors, but as to the *new opinion* I have only shewn an obscure hint from Dr. Philip, somewhat enforced by Dr. Elliotson.

After reading my paper, the critic found it safe to say for himself, that "solutions of the œsophagus are also common," but in a subsequent criticism I find M. Louis, and the reviewer after him, equally at fault in this very matter. In phthisis, the œsophagus is found "pretty frequently coated with pultaceous exudation—a condition not productive of any particular symptoms." This is merely a dissolving of the cuticle *after death*.

I should now, sir, have done, but that I catch another evidence of glaring fault, the like of which will, I conceive, ever attach to the pernicious system of anonymous criticism in science: I mean the assumption by the critic of as much of the author as the critic thinks creditable to himself. After M. Louis, he says, "so singularly rare is it to detect a ruptured vessel in the interior of the lung." I conclude that, occupied with counting other points, M. Louis has not seen as he might have seen, and that the critic is as little informed as many other literary folks as to the real fact. The sudden copious hæmoptysis in the last stages

inner villous coat destroyed, which may have been done by the gastric juice in the ducts of the glands which secrete it." Again, "there are very few dead bodies in which the stomach, at its great end, is not in some degree digested; and one who is acquainted with dissections can easily trace these gradations." Hunter has some remarks which seem to weaken the force of what I have quoted, but a just observer may discriminate for himself, and Hunter does not spare the blunders of the unobservant in these very matters.

of phthisis is from a visible ulceration of a large blood-vessel, usually attended with aneurismal clot in a vomica—See Guy's Museum. The red streak of purulent expectoration is ulcerated bronchus. The vicarious hæmoptysis of females is whatever the critic likes. The hæmoptysis of incipient phthisis, with general wasting, is abrasion of the vascular surface of the larynx. If the critic ask for proof, I reply in his own words, "as far as our observations extend, we feel convinced*." I suppose I have as much right to say so as one without a name.—I am, sir,

Your obedient servant,

T. WILKINSON KING.

Case of Ulceration of the Internal Jugular Vein, communicating with an Abscess. By WILLIAM BLOXAM, Esq. Communicated by SAMUEL LANE, Esq.

THIS is an interesting and curious case. A child, four years of age, was affected with scarlet fever. On the decline of the eruption, one of the glands of the neck became inflamed, and suppurated. After the abscess had been open for five days, blood began to show itself in the discharge. At first it was small in

* The case in which the critic does "feel convinced" he may, perhaps, some day explain to us. It relates to the influence of the nerves on digestion. My view of the matter may possibly be of some help to him. The nerves are certainly for feeling and for motion. Distension, motion, and a good vascular supply, are necessary for secretion and digestion. After this, who shall first say, what? I wish the critic better than convinced. In writing hastily, I have had no intention of writing offensively of one whom I do not know. Could a critic be softened, I might implore my "*old friend*," as he seems to style himself, to revise his judgments of the safety-valve, the venous pulse, the humoralism of hernia, the use of the thyroid body, the rapid flow of lymph, diseases variable, &c. &c. If my doctrines prove just, the same term will not apply to the reviewer of them. And so I ask his pardon.

quantity, but gradually became more copious, and of a venous character. The abscess was plugged with lymph, and pressure applied to restrain the bleeding. The child became irritable, and the hæmorrhage, which had at first been controlled, returned; and the child died on the fifth day.

On examination after death, the internal jugular vein was divided some way down the neck; and, "on passing a probe upward to the abscess, an ulceration of an oblong shape, of about five lines in its long axis, was observed in the inner side of the internal jugular vein, opening immediately into the sac of the abscess."

Some Account of an Hysterical Affection of the Vocal Apparatus, with several cases. By OSCAR CLAYTON, Esq.

SEVENTEEN cases have occurred to Mr. Clayton, in two groups; the first commencing in February 1841, and the second in October 1842. The subjects of them (children in a charitable institution) were attacked "with a short and almost constant hacking cough, with much pain and distress in breathing, but no expectoration; quick pulse, hot skin, white tongue, and costive bowels. After two or three weeks, during which time these symptoms withstood all the remedies applied, the cough changed to sounds varying in the different patients; in some, resembling the double action of a large saw; in two, a shrill screaming expiration, following a quick catching inspiratory effort, much resembling the cry of a peacock; in another, the sound was such as is produced by blowing into a small metallic tube. In fact, it is difficult to conceive the dissonance and constancy of these sounds."

Blisters, sinapisms, and a variety of other remedies, were tried without effect. At last Mr. Clayton resolved on imitating Boerhave's plan at Hâarlem. He had the children assembled, and gave them to know that he would apply a red-hot iron to the throat of every one who was not quite well by next morning! All, except two, ran away to their homes; but returned on the following day quite well. The two who remained continued to make the same noise as before, and were soon joined again by their companions. All other means having failed, a spatula

was dipped in boiling water and applied to the throat. With most this succeeded; but in two the symptoms continued, and it was found necessary to send them home, where they soon recovered.

Case of Erectile Tumor in the Popliteal Space.—Removal. By ROBERT LISTON, Esq. F.R.S. Surgeon to University College Hospital.

A boy, æt. 10, was admitted into University College Hospital in January 1843, under the care of Mr. Liston. He had a swelling in the right ham, which had been first observed eight years previously. It had gradually increased. A needle had been passed into it some years previously, and afterwards a seton was introduced. Various other expedients were also tried without avail.

The tumor was removed by Mr. Liston, January 6th, after two exploratory punctures; and the operation required a troublesome dissection (deep into the popliteal space), during which a considerable quantity of blood was lost.

"Examination of the tumor.—On making a section, the tumor was found to consist of a mass of most perfect erectile tissue as large as a hen's egg. This was completely surrounded by a condensed cellular and fatty matter. One part of the erectile tissue was more condensed than the rest, possibly where the seton had traversed it.

"Microscopic examination of the tumor.—Under a low power it appeared to consist of an interlacement of columns having a fibrous aspect, covered by a smooth membrane, and representing in miniature the appearance of the muscoli pectinati of the auricles of the heart. Thin valvular projections of the smooth investing membrane partially closed some of the openings between the columns. Small vessels, filled with blood, were seen running in the substance of the columns. The intimate structure of these columns, examined under a higher power, was seen to consist of bundles of waved parallel filaments. The surface of the columns was covered by a delicate squamous epithelium resembling that found on the inner surface of veins. No fibres resembling those of elastic tissue could be detected."

Analogous cases would appear to be rare, especially as regards the occur-

rence of erectile tumors in muscular structures. One somewhat similar, however, occurred to Mr. Liston at the Royal Infirmary in Edinburgh, which he briefly details. The tumor was the size of a small turnip, and was situated on the left side of the neck. It was removed by operation, and the patient did well.

Two Cases of Osteosarcoma of the Thigh Bone, requiring amputation of the limb in both instances. By R. A. FROGLEY, Esq. of Hounslow. Communicated by SAMUEL LANE, Esq.

THE above are two very good cases; but a sufficient idea of them is gathered from the title of the paper.

Remarks on Cancrum Oris, and the Gangrenous Erosion of the Cheek of Mr. Dease and Dr. Underwood, and more particularly on the Efficacy of the Chlorate of Potash in the Treatment of those Diseases. By HENRY HUNT, M.D.

THIS paper contains a very good description of *cancrum oris*, and suggests what appears to be a very useful remedy.

The disease "commences by small ulcers, either on the inside of the cheek, or at the point of junction of the mucous membrane of the cheek and gums, or in the gums themselves, separating them from the teeth: they are very tender and painful, and attended with profuse salivation; the breath soon becomes tainted with an offensive smell, not unlike the mercurial fætor: if the disease is neglected, the ulceration goes on to destroy the gums, the teeth loosen and fall out, the alveoli are laid bare; at the same time the brown ragged ulcer spreads rapidly on the inside of the cheek, the integuments over the spot corresponding to the ulcer become hard, swollen, at first white, and afterwards of a dull red colour, and shortly a black spot appears in the centre, which quickly spreads, and destroys more or less of the cheek; and if the child survive, it is sadly disfigured, and not unfrequently loses the power of opening its mouth, from the unyielding nature of the cicatrix; but more commonly, if the disease has extended its ravages to this extent, it sinks and dies."

The treatment recommended commences with a dose of rhubarb, with a little sulphate of potass and a grain of

calomel; at least the above is to be given where the soreness of the mouth is not so great as to render it difficult or impossible for the child to take it. But the chief remedy is the chlorate of potass. "The quantity of the salt that I have been in the habit of prescribing varies from twenty to sixty grains, according to the age of the child, in divided doses, in twenty-four hours, dissolved in water; the beneficial effect is often observed on the following day, almost always on the second; the disagreeable fætor soon lessens, the sores put on a healthy reparative action, the dribbling of saliva diminishes, and if there is mere ulceration it very speedily heals, if there is an eschar it soon separates, and the sore granulates kindly. In no other disease did I ever see the beneficial effects of any medicine so soon manifested, as that of the chlorate of potash in these diseases. It is sometimes advisable, indeed necessary, that the aperient should be occasionally repeated."

Several cases are then detailed in illustration, the last of which is by Mr. Cæsar Hawkins, and in keeping with the remarks previously made by Dr. Hunt.

Case of Ulceration of the Pulmonary Artery into an Abscess of the Lungs. With Remarks by JOHN DALRYMPLE, Esq. By WILLIAM CROWFOOT, Jun. Esq. Beeches. Communicated by JOHN DALRYMPLE, Esq. Surgeon to the London Ophthalmic Hospital.

THIS was a case of strumous disease of the left lung, attended, during life, by copious bloody expectoration. On post-mortem examination, the upper part of the left lung was found to be entirely occupied by a large cavity, containing half a pound of blood. Into this the pulmonary artery opened at the distance of two inches from its bifurcation, and by an aperture the size of a crow-quill.

Cases of Strangulated Hernia, reduced "en masse?" with Observations. By JAMES LUKE, Esq. Surgeon to the London and St. Luke's Hospitals, and Lecturer on Surgery. Communicated by Sir B. C. BRODIE, Bart.

THIS is an interesting paper. Mr. Luke has known so many as five cases in which reduction *en masse* has taken place—that is, reduction of the whole

hernial tumor, with its investing sac, through the aperture in the abdominal parietes. By this the part continued subject to strangulation as before. In all these cases a considerable similarity of circumstances was present; thus, in all, the hernia was inguinal and oblique, and had been reduced by the patient himself. In none was the exact nature of the case known during life, or any attempt made, by operation, to relieve it; and in all there was found, on post-mortem examination, a hernial tumor in the neighbourhood of the internal ring, reduced through the abdominal parietes, but remaining external to its general peritoneal investment. The contents, in all, were in a state of sphacelus, being strictured by the neck of the sac.

The first case which occurred to Mr. Luke was in a muscular coachman, thirty years of age, who, while driving in the streets of London, experienced the descent of a hernia through the inguinal ring on the left side. He immediately pressed the tumor, when it speedily disappeared without giving him any pain. But on his return home, in about an hour, he had pain in the bowels, with sickness. Professional assistance was had recourse to, but without relief; and he was admitted into the London Hospital rather more than three days after the above occurrence.

"He was at this time suffering from severe pain in the abdomen, and great prostration of strength. The abdomen was tympanitic and tense, attended by frequent vomiting of fecaloid matter, and obstinate costiveness, which latter had not yielded to purgatives administered in the course of the previous treatment. The pulse was weak, and the countenance pale and anxious."

It was suspected by Mr. Luke that the hernia had been reduced with its contents in a strangulated state. A consultation was held next day (August 31st), at which it was deemed prudent to abstain from any operation. Subsequently to this decision, the treatment consisted chiefly of calomel and opium: this was continued till September 4th, when Mr. Luke, who had been out of town, found his patient still alive, with the symptoms all increased. "A local indication had also now arisen, by the formation of a tumefaction along the course of the inguinal canal, which in-

duced me instantly to propose, and perform as quickly as possible, the operation of exploration which I had before contemplated.

"An incision was made over the seat of tumefaction, from which a quantity of highly offensive sanious fluid exuded, and by the infiltration of which into the cellular texture of the part, the tumefaction had been caused.

"Continuing the incision towards the internal ring, a lustreless greenish membrane presented itself, the tense and rounded surface of which extended beyond the limits of the opening made by the operation. This was at once recognised to be hernial sac, and therefore opened.

"On examining its contents, they were found to consist of a large quantity of intestine, sphacelated and reduced to a pulpy condition, so that it gave way under the pressure of the finger, introduced for the purpose of ascertaining the seat of stricture. This latter was reached by the finger with great difficulty, in consequence of its distance from the opening of the parietes. Being reached, the finger was passed through it, and, when withdrawn, was followed by feculent discharges, rendering further division unnecessary. A free vent for the discharges was made by enlarging the external wound, and the patient taken to bed. A bread-and-water poultice was applied over the part, and stimulants were administered by the mouth.

"Copious discharges continued to flow from the wound for two days, at the end of which he died; his death taking place on September 6th.

"The large hernial sac discovered during the operation, was brought more fully into view at the examination *post mortem*. It was found to occupy a considerable space just within the abdominal parietes in the vicinity of the internal ring. The fundus of the sac lay a little below its level, towards the cavity of the pelvis, while the neck (still contracted, so as obviously to have been the original seat of stricture) lay in an upward direction towards the umbilicus, and between three and four inches distant from the situation of the internal ring. The whole sphacelated contents were empty, collapsed, and in a pulpy state."

A second case is detailed, analogous to the preceding, but with this great

difference in the result—that Mr. Luke saved the patient's life. This was accomplished by an operation, in which the parts were freely laid open, the margin of the inner ring divided, the hernial tumor drawn down into the inguinal canal, and there opened. The stricture having been divided, the contents were easily reduced. The patient progressively recovered.

It is clear, from the history of these cases, that the too exclusive reliance on the absence of tumor externally, as demonstrating the absence of hernia, is sometimes highly dangerous; and, in doubtful cases, more security will be obtained from inquiries as to the previous existence of tumor in the part. Our author insists much on the expediency of a careful examination.

"The presence of sac, even without hernial contents, causes an abnormal fulness in the part, easily ascertainable by examination. The absence of such fulness in a part, when hernia is known to have previously descended, necessarily leads to the conclusion, that the sac upon which it depended has been displaced, and probably returned, together with the hernia.

"The sac in inguinal hernia, below the external ring, becomes united with the spermatic cord, whereby the latter is usually rendered indistinct and obscure. The absence of that indistinctness and obscurity implies the removal of the cause which previously produced them, and therefore that the sac has been displaced. The continuance of the indistinctness and obscurity leads to a directly contrary conclusion.

"When a hernia descends from the abdomen, the aperture through which it descends is always enlarged and dilated. This fact is ascertainable by the introduction of a finger—a circumstance which becomes available to the diagnosis in these cases.

"Should a large aperture be detected, a previous hernial descent may be inferred."

In making the examination immediately above the seat of the internal ring, some indications of reduction *en masse* having been had recourse to may be obtained. "Thus, it may be expected, that if such reduction has been effected, the inflammation of the hernial contents will cause a circumscribed pain in the seat which it occupies, while a fulness, or even the

rounded form of the hernia deeply situated within the abdominal parietes, may possibly be cognizable upon a minute examination; yet the absence both of circumscribed pain, and of fulness or rounded form, should not lead to a negative opinion; for in the first case neither pain nor fulness existed, yet subsequently a mass of strangulated intestine was discovered at the part.

"Their presence, however, may be taken as corroborative of an affirmative opinion, founded upon the manual examination previously instituted."

Proceeding with the exploration, the inguinal canal is to be laid open, by which the nature of the case will generally be fully displayed; and where there is a hernia, the neck of the sac must be freely divided, so as to leave no impediment to the reduction of its contents. Up to this time, the exploration has been unattended with any danger of importance, and without necessarily involving any disturbance of the peritoneum. The sac, we are told, should in all instances be opened, and the neck freely divided. Care must be taken, by the introduction of the finger through the neck of the sac, to ascertain the perfect liberation of its contents after the reduction.

Observations on the Medicinal Properties of the Cannabis Sativa of India.

By JOHN CLENDINNING, M.D. F.R.S.
Physician to the St. Marylebone Infirmary.

DR. CLENDINNING is of opinion that the plant above named has powerful influence in alleviating pain, whether neuralgic, spasmodic, or inflammatory, and in procuring sleep. The dose is ℥ss. or xij. of the tincture, equivalent to gr. j. of the extract, gradually increased.

On the Sugar in Diabetic Blood. By HENRY BENCE JONES, M.A. Cantab. Licentiate of the Royal College of Physicians. Communicated by Dr. NAIRNE.

In 1841 Mr. Trommer proposed a new method of distinguishing between cane and grape sugar; and according to his observations, $\frac{1}{10000}$ part of grape sugar, when added to healthy blood, could be recognized. "The delicate test of M. Trommer consists in the perfect solution of the precipitate which first

forms when caustic potash is added in excess to a solution of sulphate of copper and grape sugar, and the after formation of a peculiar coloured precipitate by heating the mixture. The first part of the test is not sufficient without the second, nor the second without the first; for cane sugar will give the same clear blue solution, without giving the peculiar precipitate afterwards; and uric acid used instead of sugar, gives the same precipitate by heat, but does not give the clear solution."

An opportunity having occurred, Mr. Jones repeated the experiment on the blood in a case at St. George's Hospital. When he put 0.15 of a grain of diabetic sugar in two ounces of clear serum, he was unable, after evaporation, &c. to detect the sugar by the above test; but when he dissolved the same proportion in urine, "the test was most sufficient." From this it is inferred that it is easier to discover sugar in the urine than in the blood, in which last, though it may exist, it may not be recognized by the most delicate test.

A few Observations on Encysted Hydrocele. By ROBERT LISTON, Esq. F.R.S. Surgeon to University College Hospital.

MR. LISTON is inclined to believe that some of the collections of fluid in the scrotum are more intimately connected with the testicle than has generally been supposed. He observes, "Some nine or ten months since, I was consulted by a healthy-looking gentleman, beyond the middle period of life, on account of tumor of the scrotum. There was plainly fluid on both sides. The largest cyst was punctured, and gave exit to some eight or ten ounces of thin fluid, which might be compared to distilled water with a little soap diffused through it. The other side of the scrotum was punctured a few months afterwards, and, as far as I can recollect, ordinary looking serum, to the extent of five or six ounces, was discharged."

"A short time since, the patient returned, to have the original cyst again emptied. About the same quantity of fluid was drawn off, and of the same quality as at first. This fluid was examined chemically, and scarcely a trace of albumen could be detected."

"On the second day, a minute quantity was put in the field of the com-

pound microscope, and my surprise was great indeed when it appeared quite full of spermatozoa; there were, besides, to be detected some of the primitive cells, in which the spermatozoa are developed, and a certain number of mucous globules."

"It is to be regretted that the microscopic examination did not take place immediately after the fluid was obtained, so as to have ascertained whether the animalcules presented their usual liveliness of motion."

In a postscript, Mr. Liston informs us that the preceding observation has been confirmed by the examination of the fluid from a small cyst above the testicle of a man 33 years of age. The fluid here was nearly colourless, and contained numerous spermatozoa, some of which continued to move for a considerable time after the cyst was evacuated.

On the Presence of Spermatozoa in the Fluid of Hydrocele. By E. A. LLOYD, Esq. Assistant-Surgeon to St. Bartholomew's Hospital, and Surgeon to Christ's Hospital.

WE introduce a notice of this paper here, though out of the regular order, because it refers to the same subject as the preceding. Mr. Lloyd also has found spermatozoa in hydrocele. Having met with one case, his attention was naturally directed to others; and he has examined the fluid drawn off in hydrocele "in about thirty cases." In two of them the fluid contained living spermatozoa.

The Spas Revisited: a Supplement to the Spas of Germany. By A. B. GRANVILLE, M.D. F.R.S. &c. &c. London, 1843. 8vo. pp. 72.

THE lapse of five years has made the supplement a necessary addition of Dr. Granville's well-known work upon the Spas of Germany. The following extract will show the agreeable style in which much useful information is conveyed.

Argument in favour of mineral waters. — "My argument to prove (against the opinion of the incredulous) that there must exist certain fixed powers in mineral waters, is neither lengthy nor complicated. You I say to the unbelieving members of this country, who smile at the *bonhomme*

of such as trust to the efficacy of mineral waters—you prescribe readily enough one, two, or more saline or chemical ingredients, dissolved in some fluid or other, with the intention and expectation of producing certain useful effects on the human frame, whereby disease may be removed; and you have often the gratification of witnessing the realisation of your expectations. But the ingredients you thus employ are natural products, and the very same which we detect in mineral waters. Consequently, mineral waters must be deemed capable of producing those useful results on the human structure which your own prescriptions are found to give rise to. But, inasmuch as nature is ever superior to art, and her chemical manipulations and solutions have invariably been acknowledged to be more exquisitely, as well as delicately accomplished, than those performed by man, it follows, that mineral waters are not only as good, but must be better than man's prescriptions for the treatment of disease, if *they* hold in solution saline ingredients." (p. 516-7).*

More than eight pages are dedicated to Baden-Baden, and its improvements.

Dining-room and hall at the Badische Hof.—"This *Speisesaal*, by the by, is a really beautifully decorated saloon, thirty feet high, newly painted *à la Watteau*, with a profusion of arabesque festoons all round, having a music gallery over the principal entrance. From three to four hundred persons might dine in the *salle*. There is another new part of this hotel, namely, the vestibule, or entrance hall, which equally deserves notice. To those who are acquainted with the covered *atrium* of the Reform Club in London, it will be sufficient to state that this covered hall of the *Badische Hof* so resembles it, that the sight of the one necessarily reminds one of the other." (p. 526.)

Wildbad can now be reached in five days from London, and for five pounds. "The English visitor who ascends the Rhine, may now secure his passage from London to a boat-station, called Knie-lingen, up that river, recently established, whence he will reach, by an omnibus, the capital of Baden, Carlsruhe, in half an hour, and thence, by

diligence or posting, get to Wildbad in the course of a few hours more." (p. 534.)

The improvements at Wildbad have been great, and have produced the desired effect.

"The influx of strangers has quintupled since I wrote in 1836, when about six or seven hundred visitors marked that season." (p. 536.)

Is heat a form of electricity?—"I cannot close this brief statement of the nature and effect of these singular waters, without adverting to a curious fact observed last year, by a patient of a philosophic turn of mind, in regard to them. It seems that, in the course of the operation consequent on the extensive alterations and improvements that are going on in the baths, the water of the *Fürstenbad*, instead of being suffered to flow out of the crevices of the rock into the bath, as hitherto, was conveyed into the temporary building by iron pipes of a small diameter, and that this process sufficed to alter very materially the physical qualities of the water, and its effects on the human frame. Can such a fact bear any analogy to that still more curious fact lately observed by Faraday and others, that the vapour of hot water, when made to issue out of a narrow, or compressed, or tortuous iron pipe or orifice, is in a different state of electricity than when issuing from a wider and straight one? If so, would not the observation made by this clear-sighted patient at Wildbad go to render more than probable the theory, that heat in the Wildbad waters is electricity, and that electricity is the real powerful agent of these waters?" (p. 538.)

At Ems there is a new *Kursaal*, besides many other important changes and improvements.

Teplitz.—"Teplitz baths are the most powerful awakers of lost energies, and disentanglers of stiff-joints, that I am acquainted with. They are of no use, nay quite the reverse, in cases which are accompanied by inflammatory action, acute pains, or spasmodic contractions. A medical man would send to Teplitz a patient suffering under rheumatic affection of some years' standing, which has crippled him, but he would not despatch thither an individual liable to be attacked by rheumatic fever. This distinction

* The paging in this supplement is a continuation of that in the second edition of the original work.

may serve as a type of the Teplitz waters." (p. 549.)

Schlungenbad water.—"The peculiar *satinizing* effect produced on the skin by this water, or, indeed, by any other in which sodaic and magnesian salts are predominant, proclaimed first by the writer of the 'Bubbles from the Brunnen,' and confirmed in my former description, has been denied by Dr. James Johnson, in his 'Pilgrimage'. Let the reader put a little carbonate of soda, or of magnesia, in the warm water of his basin, when using ablution to his hands, and he will soon perceive that the two first writers had asserted a fact," &c. (p. 553.)

Wines at the Grand Monarque Hotel at Aix la Chappelle.—"While on the subject of the table at the *Grand Monarque*, I would just whisper to my readers that they will find here such specimens of foreign wines as they would look in vain for at any other hotel. Let them ask, if they are anxious to have a treat, for a bottle, first of Geisenheimer Rottenberg, 1834, *ne plus ultra*, and better than Johannisberg; next, for one of Dremel's *nonpareil*, a species of Moselle wine, cultivated on the banks of the Saar, with a peculiar *bouquet*, highly flavoured and pleasing in taste, of a fine straw-colour, called Schwatzhofberger; and lastly, as a *bonne bouche* to be quaffed in a wide and narrow tazzas, a bottle of the *Fleur de Bouzy*, one of the most recent and fashionable specimens of champagne of the day." (pp. 556-7.)

Kissingen.—"Great improvements have already taken place here, and more are to be undertaken. Among others the old part of the *Kurhaus* is to be demolished.

"The present more modern part, at the back, will be enlarged and made to harmonize with the new. A splendid banqueting hall, fifty feet high, and large enough to admit of six hundred persons sitting down to dinner, will occupy one wing, with other adjoining smaller dining rooms for public or private parties." (p. 568.)

Dr. Granviller resides at this watering-place for a couple of months in the summer; and in consequence of his suggestions, the water of two of the springs—the Ragotzi and the Maxbrunnen—is now imported and sold in

London. The Ragotzi has been called the best saline chalybeate in Europe; but our author thinks this a very inadequate designation.

It is a first-rate remedy in dyspepsia; an excellent regulator of the catamenial secretion; and manifestly acts upon the skin. "And with all this its taste is such that it may be called a pleasant drink; for it is sharp, acidulous, from the excess of carbonic acid gas present in it, strongly saline, and gives a distinct indication of the presence of iron. So minute, however, is the quantity of the latter mineral, and so generally combined with the other saline ingredients, that though the invigorating properties of that one substance are felt, after a course of the water properly conducted, its occasional injurious and disturbing tendency in the human frame, observed in other mineral waters, has hardly ever been exhibited by the Ragotzi." (p. 564.)

The work concludes with accounts of the Spas of Homburg and Carlsstadt. At the latter, half an hour's drive from Stuttgart, "a bath, with linen, &c. is charged twenty-four kreutzers, or eight pence; and the cost of a dinner at the table d'hôte is forty kreutzers, or thirteen-pence farthing!" (p. 575.)

We strongly recommend Dr. Granville's Supplement to all who are interested in the subject of which it treats.

MEDICAL GAZETTE.

Friday, November 10, 1813.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

TEACHING AND LEARNING.

DR. JOHNSON concludes a letter to a young man lately arrived at Oxford, in these words—"It is a rule never to be forgotten, that whatever strikes strongly should be described while the first impression remains fresh upon the mind." The two processes in which the mind is mainly employed are observation

and inference, and although of course the latter is performed more frequently, and more skilfully, late in life, yet it is so far from being entirely postponed to that period, that it probably comes into action immediately after the former. An oscillation between observation and inference seems to be observable in the very earliest phenomena of childhood; and long before speech has translated its sensations into words, the child has given proof of being conscious that it finds every fact of its life is either like or unlike to some other facts which have preceded it; and when the young visitor has paid us the compliment of learning a little of the language, and seeing more of our curiosities, his observations to those who accompany him through that world of which we are old inhabitants, prove how constantly his mind is vibrating between observation and inference. It has been well observed, that "children seldomer ask a plain question than suggest a difficulty;" and this renders their society so fatiguing to the ignorant and unthinking, so exciting and instructive to the reflective and the well informed. This process is, no doubt, most evident in talkative children, but it by no means follows that it is more constant or more productive in them than in the more silent; the reverse is probably the case; for speaking may be to children what writing is to adults, a toilsome process, consuming some of the attention which they have to bestow, and rendering their thoughts less copious though more accurate. The putting of ideas into words, the subjecting both their form and texture to the oral criticism of themselves and others, is, no doubt, to children a most improving exercise—the harsh repression of which, whether from mere indolence, or to prevent a habit of talking nonsense, is often highly injurious. The un-

corrected observations, impressions, and false inferences of childhood and early youth are often treasured up silently in the mind; recurred to over and over again till they become confirmed, and serve as false points of departure for the mind; in the still voyage of thought, till rudely corrected by the storms and the currents, the rocks and the shoals, of active life. It is better to let children put what they do think into words: though the first attempts be rude, they will improve. The blank faces of parents and guardians on reading a schoolboy's letter, would be cheered by the reflection, that this most comically dull of all human compositions is an exponent, not of young hopeful's thoughts, but of so much of them as he can translate into the language of letter-writing, a language to him new and mystical. The real *opus dei*, the postscript, containing a suggestion about a half sovereign, or a hack-knife, will generally present a tolerably clear idea, vigorously forcing its way through all difficulties of style. A quarter of an hour in the field or the play-ground would also encourage the desponding parent, for his son's notions are then expressed in the vulgar tongue. The brilliant ideas and dexterous manipulations of a Faraday in working out a problem would seem rapid and tedious if the philosopher had to describe every step of the experiment in a language foreign and unfamiliar.

The mistakes of intelligence, so evident when the young speak, would be equally evident when the young are spoken to, if the speakers, in their wisdom, could find out the real impression made, and how widely it often differs from that which is intended. We hold forth from our several pulpits, flattered by the attention we receive, but forgetting that the monody so respectfully listened to, becomes, even as it leaves our lips, but

a mere pleading at the bar of private criticism; that our jury will take very different views of our arguments according as each is biassed by his knowledge, his ignorance, his passions, or his prejudices, and that counsel on the other side are to have their turn, and may enlist all these against us, and scatter our arguments to the wind.

Public lectures are like the talk of adults to children. The vacant and inattentive are a positive annoyance; it is a vexation to talk to those who will not listen, or cannot understand.

But the intelligent countenance, the fixed and attentive eye, are apt to betray the teacher into a dangerous error, that of supposing himself understood when he is not so in reality. The image conveyed to the sensorium may be accurately drawn, but the very nature of the apparatus which conveys it makes it refract every ray as it passes through; and until the mental apparatus becomes educated, false impressions are produced by the very truest information—the senses have to correct each other by experience.

Teaching resembles that optical experiment where the prismatic colours are arranged on a flat surface, which, when rapidly revolved, blends them together, and forms white light.

The teacher so arranges his facts or his reasons, that the whole, when united, shall present the white light of truth; but as he presents them one by one, the eye or the fancy is apt to rest longer or more attentively on one than on another, and the whirl of his ideas, though rapid enough to ensure confusion, fails to produce truth. Orentire objects, clearly enough drawn and coloured in themselves, may be placed in false relative positions, and resemble another well-known optical toy, where figures drawn on the same plane, and revolved, are made to look as if jumping over each other.

Some teachers have a peculiar dexterity in producing, and some observers in perceiving this optical illusion, the materials for which abound in every department of life. The great religious movement of the day, and an article in the *Quarterly* on the stocking and preserving of fishponds, might by such people be ingeniously combined, and Puseyism be denounced as a subtle device of interested parties to promote the consumption of fish, by inculcating the observance of fast-days; as Dr. Johnson was accused of using hard words in his popular essays, that his dictionary might be needed to discover their meaning.

The actual information received by a young listener on any subject cannot, then, be inferred from the actual instruction given, what is heard may be very different from what is learnt: there is a difference not only in quantity, much being lost in the mere process of pouring from one vessel into another, but also in quality, from the very nature of the receiver, and of the matters brought into combination. The testing of the various products by minute examination is a process that cannot be commenced too early, nor performed too often. When it is very long delayed there is apt to be grievous disappointment at the worthlessness of the compound produced from so many rich materials. How the whole spirit and savour of some have evaporated, how others, too hastily combined or too little qualified, have wrought fiercely on the receiver, or on each other, bursting or corroding the vessel, too feeble to contain them, or wastefully boiling over in frothy conceit and impertinence.

These are evils inseparable from the system of lecturing; from any system in which the talking is all on one side. Common sense, says an ingenious modern essayist above alluded to, is

never the product of a single mind. In the public school, the club, or the market, it may be gained at the cost of high moral qualities, but that which is obtained at the sacrifice of such qualities, instead of by their assistance, is not really common sense, it is usually mere knowledge of the world, that worst kind, which has been described as the property of mere cunning men.

When lecturers were few, and thinly scattered over the country, or even over the civilized world, they were men elected, though without ballot box, or any other machinery whatever, by the universal suffrage of the republic of letters, and those who took the trouble to go and hear them were mostly patient, diligent students; how to acquire their art was what they went to learn of the lecturer, and when they had been told how to do this, they went home and did it each for himself as best he might; but teachers have multiplied exceedingly, and as their benches must be filled at all hazards, they have some of them—may we not say, most of them?—professed to teach not only how to learn an art, but the art itself.

It cannot be denied that the art of teaching has greatly improved; but there is reason to fear that the more valuable art of learning is becoming more rare: indeed, if refinement in the art of teaching be carried much farther, the other will become needless, and finally be one of the *artes amissæ*.

The “wrangling” of the schools, once so celebrated, and the then grave questions of the schoolmen, which now seem so comical, were but contrivances for frequent examination and mutual instruction, laudable in their way and manner; the mind yearned to understand and digest the crude doctrines it received: such exercises, therefore, were most required, and their subjects were most absurd, when theory and dogma

from the chair were received as knowledge and wisdom by the benches; when logic, the right use of reason, was taught as an art, instead of as a scientific method of learning other arts; when, in fact, the art of teaching was cultivated at the expense of the art of learning.

Such periods occur from time to time, and painfully call forth their approximate remedy, which varies according to the cause and nature of the evil. Of one thing we may assure students—and who in medicine are not students—let them cultivate diligently the art of learning. It is one thing to have a subject made clear in the compass of an hour’s lecture: it is another to remember, to examine, to doubt, to be reassured, to apply, to labour, to overcome. Those who have seen much of students accustomed to the teaching of clever lecturers will know how lamentably they are wanting in the fruits of these laborious qualities. Clever lecturers, we said; men clever in teaching, men of genius, always impart something lasting to all who come near them.

UNIVERSITY OF LONDON.

B.M.—SECOND EXAMINATION, 1843.

Monday, Nov. 6.—Morning, 10 to 1.

Physiology.

Examiner, Professor T. RYMER JONES.

1. In what classes of animals does a portal circulation exist? Describe the arrangement of the portal system in each class wherein it is found.

2. How is absorption effected in the invertebrata? State your reasons for the opinion you give.

3. Describe ciliary motion. State the principal opinions of physiologists as to its cause, and the more important uses to which it is subservient in various races of animals.

4. Describe the respiratory apparatus of a perennibranchiate batrachian, and the general course of the circulation of its blood.

5. Contrast the auditory apparatus of a cuttle-fish, a fish and a reptile.

6. What races of animals possess a distinct urinary apparatus? Describe the

principal varieties in its composition and arrangement.

7. Describe the corpora Wolffiana.

Afternoon, 3 to 6.

General Pathology, General Therapeutics and Hygiene.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Mention the deviations to which the fibrin of the blood is subject in disease, giving examples, 1. of those diseases in which there is an excess, and 2. of those in which there is a deficiency of this constituent. What consequences have been occasionally observed to follow a deficiency of fibrin?

2. Give an outline of the treatment of spontaneous hæmorrhage, stating the indications to be kept in view, and the measures best calculated to fulfil them.

3. Describe the effects of insufficient nourishment on the human body, in the respective periods of infancy and manhood.

4. Translate the following passage into English:—

Sanis homo, qui et benè valet, et suæ spontis est, nullis obligare se legibus debet; ac neque medico neque iatraliptâ egere. Hunc oportet varium habere vitæ genus; modò ruri esse, modò in urbe, sæpiusque in agro; navigare, venari, quiescere interdum, sed frequentius se exercere, siquidem ignavia corpus hebetat, labor firmat: illa maturam senectutem, is longam adolescentiam reddit. Prodest etiam interdum balneo, interdum aquis frigidis uti; modò ungi, modò id ipsum negligere; nullum cibi genus fugere quo populus utatur; interdum in convictu esse, interdum ab eo se retrahere; modò plus justo, modò non amplius assumere; bis die potiùs, quàm semel cibum capere; et semper quàm plurimum, dum modò hunc concoquat. Sed ut hujus generis exercitationes cibique necessarii sunt, sic athletici supervacui: nam et intermissus propter aliquas civiles necessitates ordo exercitationis corpus affligit; et ea corpora quæ more eorum repleta sunt, celerrimè et senescunt et ægrotant. (Celsus, Lib. i. Cap. i.)

Tuesday, Nov. 7.—Afternoon, 3 to 6.

Medicine.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Describe the anatomical characters of arachnitis. What are its symptoms?

2. Explain bronchial or tubular, cavernous, and amphoric respiration, mentioning the pathological conditions on which they respectively depend.

3. In what diseases do ulcerations of the alimentary canal chiefly occur? Mention the symptoms by which these lesions may be recognised. What circumstances would

lead you to infer that intestinal perforation had taken place?

4. Sketch the treatment of measles, including that adapted to the mild as well as to the more severe forms.

5. Describe the principal morbid alterations of structure to which the spleen is liable.

6. To what order in the classification of cutaneous diseases does acne belong? Mention its diagnostic characters and varieties.

Wednesday, Nov. 8.—Afternoon, 3 to 6.

Forensic Medicine.

Examiners, Prof. DANIELL, Dr. PEREIRA, and Dr. RIGBY.

1. What are the characters by which you would distinguish spots of blood upon iron from common rust, and what is the principal ambiguity to be guarded against?

2. Under what circumstances may lead be acted upon by water, and how would you detect its presence?

1. What are the symptoms and chemical evidence of poisoning by nux vomica?

2. The death of an infant is suspected to have been caused by an overdose of laudanum administered medicinally. You are required to state the smallest dose of this liquid which, in your opinion, might produce death; to describe the symptoms which would arise; and, lastly, to state how you would proceed chemically to detect opium in the untaken portion of the medicine.

Three women are brought before you, in whose cases you are required to give your opinion as to the presence or absence of pregnancy on the following data:—

No. 1 is a single woman. No. 2 is married, and the mother of three children. No. 3 is married, and has had six children, the youngest of them is six years old.

No. 1 denies that sexual intercourse has ever taken place. The last appearance of the menses was on the 1st of last September, and then very sparing; the areola is dark, (she is a brunette, and is subject to irregular menstruation, with much pain) there is no perceptible abdominal enlargement; the os uteri is easily reached; it is round and seems closed, and its lips tumid and soft; the cervix is also soft, and of the full size and length.

No. 2 states that her husband, a sailor, left home on the 8th of last May; the last appearance of the menses was on the 22d of May. There is a decided enlargement of the abdomen, the tumor reaching nearly up to the umbilicus. She denies that she has felt any movements like those of a child, nor have you satisfactorily detected any with your own hand. The os uteri is high up in the hollow of the sacrum; it is soft, round, and does not admit the tip of the finger; the

cervix is shortened, the uterus above it feels enlarged, and a moveable tumor within it is indistinctly felt. There is an areola, but she is of a dark complexion, and her youngest child is only a year old.

No. 3 reckons from the last appearance of the catamenia, viz. March 8; it was scanty, and there has been a slight show twice since. The abdomen is as large as in a woman at about the eighth month of pregnancy; it is firm to the feel; the breasts present no satisfactory proofs of an areola (owing to the discoloration from former pregnancies); the os uteri is in the middle of the pelvis, forming a transverse fissure; the cervix is long and firm; a solid and somewhat moveable body, of about the size of a child's head, is felt in the upper part of the pelvis. She states that she quickened in July, since which she has felt the movements of the child, which however you have not as yet succeeded in feeling with your own hand.

If you consider any of these three women to be pregnant, state the period of pregnancy; if not pregnant, what is the nature of the case? State also the grounds on which you have formed your opinion in each.

B. M.—PASS EXAMINATION.

Tuesday, November 7.—Morning, 10 to 1.

Surgery.

Examiners, Mr. BACOT and Sir STEPHEN HAMMICK.

1. How do you distinguish a carbuncle from any other inflammatory tumor? Give the most common situation in which it is found; the general constitution and age of persons subject to this disease; the symptoms and treatment, both local and general, of an extensive carbuncle, in its different stages; enumerating such circumstances as would lead you to prognosticate a favourable or fatal issue.

2. Give the treatment, both local and general, of a simple fracture of the thigh-bone, of a strong muscular man, at its upper third, the middle third, and the lower third, from the time of the accident to its final cure.

3. What are the injuries and diseased state of a testicle which requires its removal? Describe the operation of castration, with the subsequent treatment of the patient?

4. Detail minutely the method of amputating the upper arm near the shoulder-joint, and the fore-arm near the wrist, with the management of the stumps till they are healed.

Wednesday, November 8.—Morning, 10 to 1.

Midwifery.

Examiner, Dr. RIGBY.

1. Enumerate the various conditions, diseases, &c. which are capable of simulating

pregnancy, and state how they are to be distinguished from it.

2. Enumerate the unfavourable circumstances which may result from constipation, and otherwise deranged bowels, at the beginning of labour.

3. In a lingering labour, where it is ascertained that the pelvis is well-formed, what are the circumstances which will justify your waiting and trusting to nature, and the contrary?

4. In a lingering labour, as above alluded to, what means should be adopted to hasten its course before using artificial assistance?

5. What are the symptoms, causes, and treatment of Encysted Placenta?

6. Under what forms does the Asphyxia of new-born children appear, and what are the modes of treatment?

VIVISECTION.

To the Editor of the Medical Gazette.

SIR,

SINCE Dr. Hull opened the subject of vivisection in your columns, the only allusion to experiments on living animals, in a tone apparently opposed to the views entertained by Dr. Hull and myself, which I have observed, was a general reference to those of Orfila, Sir Charles Bell, and Dr. M. Hall. I will offer you a very few remarks on Orfila to-day, and probably submit a few on the experiments of the two other distinguished physiologists for your next number. As the reference has been general, so must be my observations. Most of Orfila's experiments, I believe, are related in, or were made with reference to, his work on Poisons; and whilst I trust I yield to no one in a respectful appreciation of the merits of that elaborate work, I deny that its practical utility is increased one iota by the numerous revolting experiments therein detailed. A very easy mode of testing this is the following:—Let the book be read excluding the experiments on living animals, and let the reader note his (the reader's) conclusions; let him read the experiments on animals, and then ask himself in what way the practical information he has gained is affected by the experiments. I affirm without the least fear that his conclusions will be in no respect changed. Let me, however, remind your readers that there is a great deal of difference in the experiments of Orfila. Some consist in giving poisons to an animal, noting its effects, and recording the morbid appearances; most of them involve the administration of poison, and the synchronous infliction of that which is in itself a grave injury; as separating and making holes in the œsophagus, placing a ligature around that tube, sewing up poisons in wounds, opening and injecting veins, &c.

The first class (some of which might perhaps be included amongst those which "involve nothing more than killing an animal with ordinary expedition") furnished results, which, had we not infinitely better evidence, might have been useful; but the whole has been rendered worthless, in a practical point of view, by facts in every instance collected from the human subject, and the comparative value of which, even in the opinion of M. Orfila, may be inferred from his own words: for in speaking of Saunders' work on *Digitalis*, in a foot-note, he says, that the facts are "D'autant plus précieux qu'ils ont été recueillis chez l'homme," &c. The actual fact is, that the materials afforded by medical treatment, occasional mistakes, accidents, and attempts at suicide, have furnished results, in regard to the subject of poisoning, which it is obviously impossible to educe, or even to imitate, much less to multiply by any experiments on any brute animals whatever.

It would require a volume at least one-eighth the size of Orfila's work to demonstrate this in detail. Let me, then, at some risk of dealing inexpertly with a subject which has not fallen much in my way, state the matter thus. Of course the sketch will obviously not include *all* kinds of poisoning, but it will serve to lead people to a quick and easy mode of testing the question, if they choose to read Orfila: the treatment of poisoning may be stated, I suppose, as general and particular. The general implying expeditious attempts to evacuate the poison by *mechanical* means, as stomach pumps or enemata; by *medical*, as emetics and aperients; 2dly, attempts (where not obviously contraindicated) to dilute its acrimony, or defend the surfaces in contact with it by appropriate fluids; 3dly, to avail ourselves of the chemical affinities, to form by a second body, itself innocuous, a *tertium quid*, that shall be inert, insoluble, or both; and, lastly, to combat any lesion, inflammatory or otherwise, which the poison may have occasioned. Now, sir, if in fulfilling, *quo ad*, our present knowledge, these intentions, we can deduce nothing from Orfila's experiments, but that which we can infer with much greater safety from other, and wholly unobjectionable evidence, and I challenge any man to show me the contrary, why, then, the proof that his experiments on living animals are practically useless, follows of course. I had made a list of references to Orfila's book, for the more easy reference of such of your readers as might like to consult the work with the least possible labour, but thinking that it might be misconstrued, I have not added them.—I am, sir,

Your very obedient servant,

GEORGE MACILWAIN.

9, Argyll Place, Nov. 4, 1843.

P. S.—I do not remark on the "douleurs les plus atroces," animals dying after hours of suffering, "au milieu des souffrances les plus horribles, &c." with which his narratives are interspersed.

DIAGNOSIS OF ANEURISM OF THE AORTA.

WHEN an aneurism is buried deep in the chest, and not capable of being detected by sight or touch, it does not present a single general sign peculiar to itself, and therefore pathognomonic of its existence. Cases are not wanted in which it occasioned no functional derangement or inconvenience whatever, and the first circumstance that reveals it is sudden death. There is only one unequivocal and certain sign, viz. a tumor presenting itself externally, having an expansive as well as a heaving pulsation, synchronous with the systole of the heart. Of the remaining general signs, viz. difference in the radial pulses, constriction at top of sternum, purring tremor, aphonia, dysphagia, pain in the spine, palpitation, dyspnœa, cough, tendency to syncope, terrific dreams, starting from sleep, hæmoptysis, discoloured complexion, congestions, serous infiltration, &c. &c. a large number are identical with those of organic disease of the heart or lungs, from identity of cause—obstruction to the circulation. The first seven mentioned above are however more characteristic than the others, although yet ambiguous and unsatisfactory, as they only bespeak secondary lesions, while they fail to proclaim the latent cause of the mischief. But when they coincide with the results of auscultation, they lose their ambiguity, and rise into real importance; for the general and stethoscopic signs reciprocally borrow a precision and certainty, of which, when taken separately, they are destitute.

Physical signs.—The most direct or positive symptoms of aneurism are derived from the impulse and murmur caused by or within the diseased vessels. Of course I mean when taken conjointly with those arising from compression or destruction.

When dilatation of the arch and ascending aorta is present, its presence is indicated, 1st, by a constant pulsation above the sternal ends of the clavicles; strongest at the side the enlargement is confined to; but this pulsation is never communicated to the costæ or sternum, unless the tumor is extremely large. 2dly, A hoarse murmur, loudest in the same situation, is generally present, synchronous with the systole, and having the same duration; this sound, like the impulse, will vary with the situation of the dilatation. I said loudest above the clavicles, because this fact greatly assists in

distinguishing it from that which proceeds from diseased aortic valves. It is also usually distinct on the back. 3dly. A purring tremor felt likewise above the clavicles, strong in direct ratio to the force of the circulation and to the rough and unequal state of the aortic membrane.

I am not aware of any general symptoms, or combination of them, characteristic of this affection.

Diagnosis.—*False aneurism.*—Sacculated thoracic aneurism indicates its presence by a pulsation both above and below the clavicles (stronger below). In the front the pulsation is more forcible over the tumor than at any point intermediate between it and the heart, or indeed than the impulse of that organ itself; when the disease is situated either in the beginning or middle of the arch, the impulse is strongest above and below the right clavicle and at top of the sternum, the base of the neck on that side being puffed and swollen. When situated at the beginning of the descent, the pulsation, &c. incline to the left. But if it affects the descending portion, the impulse is rarely felt in front, it buries itself so deeply in the lungs (as in two cases to be related), and even on the left side of the back the impulse will be much masked until the tumor becomes very large, and comes in contact with the costæ; however, percussion ought to indicate the presence of a solid body much earlier.

Murmur in old aneurisms is always discoverable to a sufficient degree, at least to be very much depended on; when, however, an *abrupt* murmur is perceptible on the back, over the seat of dulness, it ought to have considerable weight. But if on the back the murmur is more abrupt and rasping than the ventricular systole in the præcordial region, then the evidence of aneurism is almost positive.

Both in considerable dilatation of the cross and sacculated aneurism I have observed another symptom easy of appreciation, viz. by placing one hand flat over the suspected seat of disease, and the other opposite to it on the back, I have been enabled to assist, or rather render positive my diagnosis, which was otherwise doubtful.

The sensation of an expansive heaving being communicated to the hands (I do not mean impulse), all or either of the following general signs may be present: a pulsating tumor externally, dulness on percussion, dysphagia, aphonia, pain in the spine, aching and numbness of left arm, weight in the chest, inequality or extinction of left radial pulse, swelling at root of neck, double impulse of the heart when the tumor is behind it, and specially a peculiar mode of respiration caused by a pulsating body pressing on the bronchi.

The following are the sources of fallacy

which must be excluded, *negatively at least*, from our premises, before we can safely attempt a conclusion, or arrive at a correct diagnosis:

1st. Glands and other tumors receiving pulsation from an artery beneath them.

2d. Hydropericardium.—The impulse in this case is never exactly synchronous with the ventricular systole, nor has it the powerful expansive heaving of aneurism, the shocks being of unequal force, and alike wherever heard; whereas in aneurism the impulse is stronger over the heart, than in the space between.

3d. Hypertrophy, with dilatation of the heart.

4th. Subclavian and carotid aneurism, from which it may be easily distinguished.—*Dr. O'Eryen, in Dublin Journal.*

PROPERTIES OF BEBEERINE.

As regards the features which are characteristic of bebeerine as a therapeutic agent generally, I (Dr. MacLagan), think that the cases related entitle us to consider that it is a marked antiperiodic and tonic, and consequently that there is good reason to believe that it may be applied to the same purposes for which the more expensive sulphate of quinine is employed.

Contrasted with quinine, I should say from what I have observed in my own patients, that it is not so liable to excite the circulation. Dr. Watt, in one of his letters, writes to me—"I took ten grains of the sulphate on going to bed on 27th November, by way of trial. The taste was not more bitter than quinine, but continued much longer in the throat. It has a very astringent taste, causing the point of the tongue to have a leathery feel. I felt some fulness about the ears during the night, but no ringing. The same quantity of quinine would have made my ears ring for a whole night, and made me feel nervous next morning. After the bebeerine I had no nervous feelings whatever."

In a subsequent letter he says, "Whether or not the bebeerine affects the head like quinine, still remains a question. Dr. Blair's patients said not—mine that it did. But as my patients were stupid Portuguese, and had to be enquired at through an interpreter, who put a leading question, they may have answered yes, from politeness."

I may state that the astringent taste observed by Dr. Watt is characteristic of the salts of bebeerine, and is in no way connected with any adherent impurity, nor does it confer on the sulphate any astringent action on the bowels. On the contrary, in most of the cases in which I used it, the

bowels have remained regular without medicine.

It is unnecessary to say any thing further here, as to a secret medicine, extensively circulated under the name of "Warburg's Fever Drops," and which, as I have elsewhere stated, I believe to be a tincture of *bebeeru*, probably of the seeds. Like any other preparation of *bebeerine*, it may answer for treating intermittent or remittent fevers; but the supposition that it is applicable as a specific remedy to such a disease as our common continued fever, is a fallacy too obvious to require comment.—*Edin. Journal of Medical Science.*

INTERESTING EXPERIMENT.

THE *Courrier Français* states, that a most curious experiment has been lately made in the hospital of the Salpêtrière at Paris with a machine invented by Dr. Payerne, called the purifier, the object of which is to purify the air, without renewing it, in hospitals, prisons, mines, diving bells, and, in general, in all places where the air has been vitiated. This experiment, which excited the greatest interest from the important results to be derived from its success, was witnessed by deputies from the Academy of Sciences, the Administration of Hospitals, and by several distinguished chemists and physicians. Dr. Payerne entirely succeeded in what he proposed, viz. to purify the air completely in an enclosed space without communication with the external air. The thermometer, at the same time, descended several degrees. Dr. Payerne proposes, in a few days, to make an experiment with his machine on a diving bell in the Seine, by which the divers may remain an indefinite time under water without communication with the atmospheric air.

CASE OF HYDRO-PERICARDIUM:

PUNCTURE AND EVACUATION OF THE FLUID, &c.

A YOUTH, 19 years of age, was seized with sharp pain in the right side of the chest, great dyspnoea, and other signs of pneumonia. He had been ill for some time when he was taken to the Vienna Hospital; the active stage of the disease had already passed over, and was succeeded by the signs of effusion within the thorax. The face had become puffy and oedematous, and expressed intense anxiety; the breathing was short, hurried, and accompanied with a rattling noise; there was a frequent cough, which

brought on a pungent pain in the left side; the left jugular vein was much swollen, &c. On percussion, the whole extent of the sternal region of the chest was found to be very dull; under the left clavicle, however, and along this shoulder on to the axilla, the sound elicited was clear; but again it became dull over the lateral region of the chest. On the right side, the resonance was normal, except at the lateral parts from about the fourth rib. The liver was found to extend beyond the edge of the false ribs, for at least two finger-breadths. The impulse of the heart was very feeble, and the sounds of its action very indistinct. There was a strong respiratory murmur (the expiratory one being unusually loud) heard over the whole extent of the left side, except in the cardiac region, and also over the front of the right side: lower down, however, it was scarcely audible. The pulse was rapid, small, and irregular; the urinary secretion was scanty and deep-coloured. The pulse was rapid, small, and irregular; the urinary secretion was scanty and deep-coloured. The patient complained of a continual sense of pressure at the epigastrium, especially when he lay on the left side: firm pressure over the heart gave rise to a sharp pain in that region.

The diagnosis formed was that there was a considerable effusion within the pericardium—the consequence of pericarditis—causing the compression of the inferior lobe of the lung; also slight exudation in the right pleura, with an infiltration of the pulmonary parenchyma, the result of pneumonia; general bronchial catarrh.

As symptoms of a peritoneal effusion made their appearance in the course of a few days, it was determined to have recourse to *paracentesis pericardii* without delay.

The puncture was made (5th August) in the fifth intercostal space, about two inches from the left extremity of the sternum, and about one inch below the mamma—in order to avoid more certainly wounding the internal mammary, or any of the great vessels. At first, only a small quantity of reddish fluid escaped by the canula; but, by using gentle compression, as much as three pounds (*livres*) was discharged. The patient experienced great relief; and the double sound of the heart, as well as the "*bruit de frottement*," were heard much more distinctly immediately afterwards. Next day, symptoms of inflammation in the lower lobe of the left lung made their appearance: the patient was therefore bled. For several successive days, there was a manifest increase of the pericardiac effusion. Digitalis and iodine were administered, and mercurial frictions were employed at the same time.

As the disease was manifestly making progress, a second operation was performed

(22d August); but on this occasion not more than three-fourths of a pound of fluid flowed out. Again there was an attack of pneumonia; but it was fortunately subdued without much difficulty. The state of the patient seemed to improve until the 4th of the following month, when the dropsy of the pericardium and also of the peritoneum began rapidly to increase. Death took place on the 12th.

Dissection.—Adhesions of the right pleura, and considerable effusion in both cavities of chest—to the amount of between eight and nine pounds (livres) on the left, and of about five on the right side: both lungs compressed and flattened against the spinal column, and several patches of tuberculous deposit throughout their substance. Pericardium adherent to the heart over a great extent of its anterior surface; and several ounces of fluid within its cavity. The heart itself large and flabby; its cavities, especially those on the right side, considerably dilated, and filled with coagulated blood. From 15 to 16 *livres* of serosity within the peritoneum; this membrane somewhat thickened in several parts; the liver enlarged, dense, and of a brown-red colour. —*Schmidt's Jahrbucher.*

REMARKS.—Most British physicians will unquestionably disapprove of the practice adopted in the foregoing case. No advantage could be reasonably expected from discharging the pericardiac fluid, while both cavities of the chest contained so much. We are not aware that paracentesis of the pericardium has ever been performed in this country. Without going so far as to reprobate the operation under any circumstances, the cases, we should think, in which it is justifiable, must be of exceedingly rare occurrence. It is a great error with many medical men to be desirous of doing something in every case: they seem to forget that there is quite as much skill required in knowing when to do nothing, as to employ vigorous treatment when this is called for.

A propos, we remember an anecdote of a clever but sarcastic surgeon, which may deserve reporting. On one of his colleagues, who was rather a busy meddling sort of practitioner, remarking, in reference to a dangerous case in the hospital, that in his opinion such and such were the "indications of treatment" to be pursued, he very coolly observed, that, in his opinion, "the only indication was death." The lesson suggested is a useful one; *ne quid nimis.*—*Med. Chir. Review.*

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

THE first meeting of this Society will be held on Tuesday next, Nov. 11, at half-past

eight, when the following papers will be read:—

An Account of Two Cases of Rupture of the Ureter or Pelvis of the Kidney, followed by large Effusion of Urine into the Abdomen. By Edward Stanley, Esq. F.R.S., President of the Society.

Two Cases of Ulcer of the Stomach, producing circumscribed Abscesses in the Peritoneum. By Edward J. Seymour, M.D. F.R.S.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, November 2, 1843.

W. Spackman, Lutterworth, Leicestershire.—D. Perkins, Bridgewater, Somerset.—H. C. Hastings, East Dereham, Norfolk.—E. W. Pilgrim.—W. Smith, Newport, Bucks.

Wednesday, Nov. 8.

William Few, Huntingdon.—Henry Hayton Radcliffe, Liverpool.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, October 28, 1843.

CLINICAL OBSERVATIONS
ON
SECONDARY SYPHILITIC AFFEC-
TIONS OF THE SKIN.

By B. PHILLIPS, F.R.S.

THERE are in the Infirmary, at this time, three women and one man suffering from secondary syphilis affecting the skin. Some remarks on these affections may therefore be useful.

A. B., aged 32, has been under treatment many weeks for the most aggravated case of syphilitic rupia I have ever seen: it had been preceded by a vaginal or urethral discharge, and she believed by a sore. It affected a great part of the trunk and the extremities. The syphilitic cachexia was strongly marked. Her eyes and hair were dark; and they contrasted so strongly with the ashy character of the face, as to produce a very singular expression of countenance. The mucous surfaces were so irritable, the pulse so small, and the paroxysms of hectic so frequent—continuing for a week, and then abating,—that it was deemed prudent to trust to good food, wine, and sarsaparilla. Under this treatment, there was a very slight improvement at the end of six weeks. Iodide of potassium, in four-grain doses, was then associated with the sarsaparilla, and was continued for a month without any marked improvement. Recourse was then had to the proto-iodide of mercury, in half-grain doses, twice a day, with four grains of Dover's powder. At the end of a month the amendment was very remarkable: the appetite and the complexion improved; the redness around the rupia scabs, and the stiffness of the joints, were lessened; and from that time her progress towards recovery was steady; but there was so much damage to be repaired, that several months elapsed before the cure was complete: indeed, long

after the cicatrization of every sore, she was not discharged, from her inability to move about; but gradually this inconvenience left her.

H. O., a sailor, aged 19, I treated for primary syphilis. He had a well-marked Hunterian chancre, with bubo. He was treated, after the first week, with one-grain doses of calomel and a quarter of a grain of opium, twice a day, until the system was slightly affected. The ulcer healed well, and the induration disappeared, but the bubo broke. He embarked, as soon as the discharge from the bubo ceased, on board an Indiaman, which had to touch at the Bermudas. Before he arrived there, he was laid on his back, with pains in his bones. He was invalided and sent home, and arrived with his face covered with rupia scabs. He was ordered generous diet, a bottle of porter a day, and a pint of decoction of sarsaparilla. Under this treatment every scab was thrown off, and all his pains left him within seven weeks.

H. C., aged about 30, I treated for gonorrhœa, about which there was no other peculiarity than the occurrence of a copaiba eruption. Seven weeks from the contagion, he presented a well-marked exanthematic syphilitic eruption of the skin, and an excavated ulcer on the tonsil. At first he took iodide of potassium and sarsaparilla; but as the use of those medicines seemed to have no effect upon the eruption, recourse was had to the proto-iodide of mercury, with Dover's powder; and after three weeks of that treatment, the eruption disappeared, and the tonsil was quite well.

E. D., aged 24, you may recollect, was admitted for an ulcer near the margin of the anus. There was no appearance of disease about the sexual organs. The ulcer was very suspicious looking, but it very quickly yielded to black wash, and hyd. c. creta, with Dover's powders. During the next fortnight she complained of being out of health; at the end of that time the skin became

covered with papular syphilis, and syphilitic vegetations were developed by the side of the chitoris. She took proto-iodide of mercury—one grain every night, with one-third of a grain of opium,—and decoction of sarsaparilla. The vegetations were soon got rid of by being touched with aromatic vinegar. At the end of a month all that remained was slight discolouration where the papule had been seated.

M. G., aged 34, was under treatment for very severe orbital neuralgia. It resisted bark, steel, and opium. While under treatment, the surface of the body became covered with well-marked syphilitic psoriasis; he had an ulcer on the tonsil, and several acutely sensible white points on the margin of the tongue. It appeared that ten years had passed away since he had any disease of the genital organs: at that time he had a common chancre, which quickly yielded to blue pill. He had been married eight years, had several children, and both his wife and children were perfectly free from any apparent taint of syphilis. He took the bichloride of mercury, one-sixth of a grain twice a day, for six weeks. In the first forty-eight hours he became free from neuralgia, and the tenderness of the tongue and the throat disappeared. By the conclusion of the sixth week, during which he took the mercury only once a day, nothing of the disorder remained but slight discolouration where the patches of psoriasis existed. Many weeks had not passed before the tongue and throat resumed their former condition, and the spots became deeper. He resorted to the bichloride again, and followed it up for about five weeks, when he appeared to be quite well again. Many weeks did not pass without a new visitation; but on this occasion it came in the shape of neuralgic or rheumatic pains, stretching over the abdominal parietes. In this extremity recourse was had to calomel and opium, and pretty smart salivation was set up. Gradually the symptoms subsided, but the system was not rid of the enemy: irritation, and probably ulceration, was set up in the rectum, which eventually yielded to hyd. c. creta, which affected the system. This case was extremely obstinate: the affection had existed so long that it had become as it were a part of the economy.

A. W. had small, whitish, irritable points around the edge of the tongue, and a well-marked excavated ulcer of the tonsil; he had also three patches of syphilitic lepra of the scalp. Besides these symptoms, he had another, which I have only seen in one other case—a conversion of the integument on the inside of the thigh into a horny tissue—the appearance being like that which I have seen on the legs of old women in France who are accustomed to sit over chafing dishes. The patch on the inside of

the thigh was about the size of the palm of the hand; there was a second patch on the inside of the leg, along the tibia. He was treated with iodide of potassium and sarsaparilla; but before the affection was quite got the better of, he had to take three courses, of six weeks each, of those medicines, and to be treated with mercury also. On each occasion the iodide, with sarsaparilla, acted very well; but after the third re-appearance I thought it better to try calomel, which, however, never gave evidence of affecting the system, though in the end he took three grains three times a day. However, the treatment was successful; and the horny degeneration was gradually but very slowly dissipated.

You are well aware that a person who suffers from what is known as primary syphilis may, after a certain lapse of time, present another form of disease—a consequence, as we believe, of the former; and which is known as secondary or constitutional syphilis. Of these a great many specimens are observed here in the course of a year.

The most obvious signs of constitutional syphilis are certain cutaneous eruptions, but there is no necessary accompanying character of the eruption which infallibly marks it. The character upon which we are accustomed to rely most—and it is the most constant—is a certain modification of colour; and in the greater number of cases it is, no doubt, a good point. This modification of colour is a more or less decided coppery redness, which, when once the eye is accustomed to it, rarely leads to error. But as this colour may be much modified, or even entirely wanting, we might fall into error if we regarded all eruptions in which this character was absent as necessarily not syphilitic. Indeed, in vesicular syphilis, a rare form of the disease, the coppery tint is often indistinct, if not wanting. Sometimes, though more rarely, it is wanting even in the pustular and the squamous forms of the disease. In the tubercular, the papular, and the maculated forms of the disease, the copper tint is much more rarely wanting. In such cases, therefore, the coppery redness is a much more certain diagnostic mark than any other. It may be, however, that at first the eruption presents a simple redness, the coppery tint not making its appearance until a later period. Still, in the great majority of cases, there is present a very characteristic tint: it may not be a coppery red; it may be even a brownish or yellowish grey. By some pathologists the colour is supposed to depend upon extravasated blood—to be, in fact, something like ecchymosis; by others it is regarded as a change brought about in the pigmentary deposit, and this seems the most reasonable way of explaining it.

Some writers have maintained that cu-

taneous syphilitic eruptions have a tendency to arrange themselves in a circular form. A large number of non-syphilitic eruptions take that form, and therefore there is nothing upon which you can rely in this respect. The general diffusion over much of the surface of the body is a better characteristic. If to these features we add the common persistence of the affection after simple treatment, its disappearance after specific treatment, and the frequently long continuance of the colouration where the spot existed, and you have points enough to feel no doubt that, in the general appearance of syphilitic eruptions, there is something which usually impresses upon the mind a conviction that the affection is syphilitic, even before you obtain a history of the case; and any one who has seen many cases will rarely be in error. Still you will experience difficulties. The patient will positively deny that he has ever had primary symptoms. He may have had them, but so long ago—and in his mind there appears such an absolute want of connection between the two affections—that the recollection of it does not occur to his mind. Again, the social position of the patient renders it prudent, as he conceives, to conceal the circumstance. In fact, the light of history is altogether wanting; and we have to rely upon the features to which we have before alluded. In some doubtful cases we have recourse to mercury as a kind of test: if under its use the affection improves, it is at once regarded as syphilitic; if it resist, the presumed syphilitic nature is rejected. A non-syphilitic affection may improve under mercury; a syphilitic affection may for a long time resist its influence: witness the case of a patient now in the house with well-marked syphilitic lichen: she has been twice salivated. The case of the sailor, equally well marked, got well under sarsaparilla and a generous diet.

A great many men have advocated the opinion that what we regard as secondary syphilis is not a consequence of primary syphilis, but of the treatment which has been employed for its cure—mercury. Now have any of those who support that opinion known what we regard as secondary syphilis to occur where a patient had not been the subject of primary syphilis, even though mercury may have been pushed so as to induce profuse salivation? You have before you now a case of well-marked secondary syphilis, while the patient has not taken any mercury.

Cazenave gives 143 cases of secondary syphilis. Of these the primary affection had not been subjected to any treatment in 41 cases; treatment unknown in 5; simply antiphlogistic in 51; in the remaining 46 mercury was used.

It is clear, then, that whatever treatment

is followed, secondary symptoms will appear in a certain proportion of cases. The Swedish tables showed that the proportion of cases of secondary affections was much greater after the mercurial than the non-mercurial treatment. This may be true; but I should be glad to see the experiment fairly tried, the mercurial treatment being prudently employed, before I accept the return made by those who advocate the non-mercurial system. It would almost seem that certain persons have a syphilitic temperament or disposition; and in them, no matter what treatment may be employed, secondary disease will occur, and will prove very obstinate. In most cases moderate mercurial action exercises a prompt and decided influence upon it; but in some it is necessary to use mercury again and again before it can be quite dislodged from the system.

You have had opportunities of seeing that primary syphilis does not always present a similar character; you have possibly heard that there is a plurality of poisons: into that question we do not propose to enter at present. But it is certain that the features of the primary affection are very variable. You have also had ample opportunities of observing that the secondary affections present quite as much diversity of feature. Now those circumstances have given rise to an opinion that the particular form of primary disease has a corresponding form of secondary affection.

Few men have bestowed more attention on secondary syphilis in general, and upon this point in particular, than Mr. Carmichael; few persons, I apprehend, are better qualified to observe; few, indeed, have enjoyed better opportunities for observation. From an attentive consideration of a vast number of cases, during many years, he concluded that a particular form of primary affection was followed by a particular form of secondary disease: "that the syphilitic chancre is attended by the scaly eruptions lepra and psoriasis, an excavated ulcer of the tonsils, and pains and nodes of the bones." "That the simple ulcer without induration, raised edges, or phagedenic surface—gonorrhoea virulenta, and excoriation of the glans and prepuce, are followed by a papular eruption, which ends in desquamation; pains in the joints resembling those of rheumatism; soreness of the fauces, and frequently swelling of the lymphatic glands of the neck; but that, in a vast number of cases, not a single instance was observed in which nodes were attendant upon this eruption." "That the ulcer with elevated edges, in the few instances in which I had an opportunity of tracing it to its constitutional symptoms, was followed by a pustular eruption, which terminated in mild ulcers, pains in the

joints, and ulcers in the throat, but no appearance of nodes; yet that the instances in which I had an opportunity of witnessing distinctly the connection between the primary and secondary symptoms of this poison were too few to form a decided conclusion with respect to this particular." "That the phagedenic and sloughing sores are generally attended by constitutional symptoms of peculiar obstinacy and malignancy, viz. pustular spots and tubercles, which formed ulcers, that spread in general with a phagedenic edge, and heal from the centre; extensive ulceration of the fauces, particularly of the back of the pharynx, obstinate pains of the knees and other joints, while nodes are frequently present, and the bones of the nose are occasionally affected." "That when an eruption, no matter what its character may be, is on a surface which is opposed to another, as on the fossa of the nates, upper part of the inside of the thigh, or in the axilla, the spots, if they do not ulcerate, extend into soft moist elevations of the cutis, which ought to be treated according to the nature of the disease to which they belong."

Such are the ideas of Mr. Carmichael—to which I cannot subscribe; at the same time I admit the subject to be surrounded with great difficulty. For instance, if I show you cases opposed to the rules above described, objections may be raised. If I shew you a case of gonorrhœa virulenta, followed by a well-marked squamous affection, with a fair excavated ulcer of the tonsil—and such is one of the cases before you,—it may be said, did the so-called gonorrhœa depend on a syphilitic ulcer within the urethra, or have I any proof that there has been no syphilitic ulcer externally? In the case of the sailor with syphilitic rupia, I treated the primary ulcer, and no better marked Hunterian chancre could be seen. The extremely aggravated case of rupia you so long saw in the women's ward, succeeded to a small syphilitic ulcer. It is hardly necessary for me to refer you to a number of cases to prove that you cannot confidently predicate, from the primary affection, what will be the form of secondary disease which may result from it; but as an ordinary rule, with very many exceptions, Carmichael is very possibly correct. Cazenave reports that, out of 58 cases of secondary disease succeeding to gonorrhœa, 23 presented the tubercular, 16 the pustular, 7 the squamous, 2 the exanthematic, 4 the vesicular form of the disease. Taking the whole of his cases, amounting to 146, they are thus distributed:—After chancre, 37 cases, of which 19 tubercular; 6 pustular; 5 papular; 7 squamous. After gonorrhœa, 54 cases, of which 23 tubercular; 16 pustular; 6 papular; 7 squamous; 4 vesicular; 2 exanthematic. After chancre and gonorrhœa, 50 cases,

13 tubercular; 21 pustular; 7 papular; 2 squamous; 5 exanthematic; 2 vesicular.

I have no doubt of these observations having been carefully made, but there are reasons why we should not regard them as conclusive evidence that the rule laid down by Carmichael is incorrect. In a large number of the cases of secondary syphilis treated by us, we have had no opportunity of treating or even seeing the primary affection, and it is certainly unsafe to trust entirely to the description of his case given by a patient. With reference to male patients, we may receive the statement, whether they have had a sore or not, whether they have had a discharge or not, but in the case of a female patient what is it worth? she may say she has had a discharge: even supposing it to be gonorrhœa, what proof have we that she has not had a sore at the same time? Carmichael's opportunities of observation were unusually favourable; he belonged to an hospital where a large portion of the patients were treated for the primary symptoms, and where they came to be treated for the secondary affection; he had therefore uncommon opportunities for comparing and connecting one with the other.

In some of the cases to which we have referred, the constitutional affection has appeared during the existence of the primary disease, but generally some weeks, often some months, and occasionally some years, pass away between the disappearance of the primary disease and the occurrence of the secondary affection. Sometimes, for weeks or even months, there is failing health, for which it is difficult to account, and it is then a great satisfaction to find the cause of suffering unmasked by the occurrence of a syphilitic eruption on the skin. A gentleman living in this neighbourhood had intense orbital neuralgia, for which he took bark, iron, and opium, without any permanent relief; suddenly his skin became covered with well-marked syphilitic psoriasis; bichloride of mercury was exhibited, and his neuralgia was quickly cured.

One of the most singular circumstances connected with secondary syphilis is, the long time which may elapse between the period of the primary and secondary disease. I have had under treatment a case where ten years had passed between the occurrence of the primary ulcer and the development of extremely well-marked syphilitic psoriasis. And in this case there were many circumstances to confirm the truth of the statement, and there was an absence of any reasons for concealment. But ten years is a small interval, compared to many in which the history seemed to be equally authentic. Cazenave relates cases where thirty or forty years have passed between the primary and secondary affection. These

histories have been discredited by some medical men, who have maintained that there must have been an intervening attack of primary syphilis, and by others who have expressed doubts as to the supposed secondary disease being syphilitic at all. Still, spite of those doubts, competent and experienced observers are convinced of the affections being secondary syphilis, and of the length of the interval which had elapsed. In cases where months or years have passed since the occurrence of the primary disease, and where the virus is, as it were, asleep in the system, it usually happens, at least that is my experience, that so long as the person continues in good health the syphilitic taint is not manifested, but when the general health becomes damaged by the occurrence of some other disease, then the virus seems awakened; the constitutional power of resistance is lessened, and the characteristic symptoms are developed. If the disturbance in the general health be owing to some affection of the mucous surfaces, it is upon them that the secondary affection is apt to manifest itself. If rheumatism affect a joint in a person whose constitution is tainted with syphilis, it is the articular system which may suffer; an injury to a bone may determine the manifestation of the disease on that part.

It has been a matter of question whether the particular form of the primary affection has any relation with the time of manifestation of the secondary affection. Martins sought to make out a mean of the time which may elapse between one and the other; he found that a longer time elapsed between the attack of a gonorrhœa and the occurrence of the secondary affection, than in any other form of disease, but the number of cases where the interval has been very long has been too small to justify much confidence in the results. The fact of the great discrepancy between the results afforded by the examination of about an equal number of cases at St. Louis, by MM. Martins and Legendre, clearly show that circumstance. Cazenave collected more than twice the number of cases observed by them, and the results approach to something near a mean of those of the other two.

It is not uninteresting to ascertain what is the particular form of primary disease which is most quickly followed by secondary symptoms. Cazenave's experience is in favour of the following order of development: Chancres with bubos, chancre, chancre and gonorrhœa existing together, gonorrhœa. The cases on which he observed are probably too few to lay down accurate rules; they amounted to only 153. Besides that, his mean interval between the primary and secondary affection is probably too long, and the result is of little value; it is little

more than an object of curiosity. Thus, the mean interval between a chancre and its secondary affection is $4\frac{1}{2}$ years; the extremes 1 month and 24 years. Now, my mean is very different, because my longest interval is 10 years; my shortest nil; my mean under a year; and yet I conclude in both cases the deduction is fair. An accident may give one man an opportunity of seeing among his earliest cases one where the interval is very long. If he takes a mean from only a few cases, the interval may be very long. The only fair way is to take a very large number of cases, and then I am persuaded the mean interval would be very far under a year. Indeed, in the vast majority of cases, the interval is very much under six months. Then, again, as to the form of secondary disease, which is most tardily developed, Legendre, Martins, and Cazenave, give it in favour of the tubercular form, which has a mean of about seven years. You have now before you two cases (female) of tubercular syphilis. In one the disease was manifested before the patient was discharged from treatment for the primary disease; in the other, the interval between her discharge for the one, and her admission for the other, was only two months. Still I have no doubt that those authors made a fair deduction from the facts in their possession. Martins and Legendre have observed, that the pustular form of the secondary affection is that which is most speedily developed. I make out, on the contrary, from my opportunities of observation, that the papular and squamous forms succeed most promptly to the primary affection. Again, I am not agreed with Cazenave on another point: he says, that in 157 cases of secondary disease, 60 succeeded to gonorrhœa, with or without bubos. Of 73 cases of secondary disease I have registered, in only 7 instances could it be properly referred to gonorrhœa.

It has been said, "the treatment of secondary syphilis should be almost similar to that of the primary disease;" that, however, was the dictum of a man who regarded mercury as the remedy for the primary disease. In the present day, it is notorious that by one portion of the profession primary syphilis is treated without mercury. If they adopted the before-named principle, they ought to treat the secondary disease without mercury. It is not so, however; even the advocates for the non-mercurial treatment of the primary disease commonly have recourse to mercury in the treatment of the secondary affection.

I usually employ mercury in the treatment of the secondary cutaneous affections. For some years I relied almost entirely on the bichloride, which I have been accustomed to give in doses of from one-twelfth

to one-sixth of a grain, twice or three times a day, associated with sarsaparilla, and I have often been surprised at the promptitude of its action, especially where the mucous tissues are affected; it seems to be so readily diffused through the system; but I have again and again found that in a short time after the medicine has been discontinued the symptoms have reappeared. By resuming the medicine they again disappear, and in the end the disposition may be worn out. The circumstance induced in my mind an impression that in many cases it was necessary to induce a clear though slight mercurial action in the system, and this I have never observed under the use of the bichloride. I do not, however, mean to say, that a mercurial action fairly set up is sufficient to cure secondary syphilis; there are cases which will long resist mercurial action. I have often tried Plummer's pill; it will in most cases succeed, but its curative influence is much more slowly induced. Frictions answer well in many cases, and in hospital practice we can employ them, but in private practice patients are glad to avoid the inconvenience.

The form of mercury you usually observe me employ is a combination of iodine and mercury—the proto-iodide of mercury, and I prefer it to any other form. It affects the disease almost as rapidly as the bichloride, and I have not met with many relapses after its use. Cazenave thought it was more easily borne by patients than many other forms; he thought it did not often produce salivation. I do not know that I have found it to be borne better than the bichloride, and I have known it active in inducing salivation. The woman with syphilitic lichen is just now recovering from its effects; she took a grain daily for eleven days, when profuse salivation occurred. Still I prefer it to any other form, for the following reasons: it is more prompt in its action than any other form of mercury, except the bichloride, and its effects are more permanent than that, and on the whole I think it is borne as well as any other. I have never given more than a grain twice a day, associated with opium.

Although I rely most firmly upon mercury as a curative agent in these affections, I have not used it to the exclusion of other medicines. There can be no doubt that the iodide of potassium is a valuable agent in the treatment of secondary syphilis. No other form of iodine has succeeded so well in my hands, except the combination with mercury, but I have never exceeded ten grain doses.

Of the decoction of sarsaparilla, either alone or associated with mercurials, mineral acids, or the iodide of potassium, most men have had the opportunities of seeing the good effects.

I am inclined to believe that these several medicines act best each in a particular form of the disease, but I am scarcely in a condition to point out with confidence the case to which the particular remedy is best adapted.

I do not think we can rely on acids in severe cases, but where the symptoms are chronic, and the general health not seriously compromised, they occasionally do very well, but always best when associated with sarsaparilla. The latter decoction I have seen succeed alone in very severe cases. The case of rupia which is mentioned was of such a nature; so was a case of tubercular syphilis, represented in the wax cast before us. Where the case is a very severe one, it is upon the iodide of mercury, however, I rely. I must, however, caution you against the too precipitate use of mercury where the syphilitic cachexy is very decided—where the mucous surfaces are very irritable. In almost all such cases I begin with generous diet and decoction of sarsaparilla, reserving the mercury until the general health is somewhat improved, and the mucous irritability lessened. There are, however, few cases, whatever may be the internal treatment employed, which are not the better for the common warm water or the vapour bath, administered twice or thrice a week.

These are all the remarks I propose to make on the nature and treatment of secondary syphilis affecting the skin. I do not pretend to have completely considered the subject; all I sought to do was to bring under your notice the more salient practical points, leaving it to yourselves to fill up the picture; and this I trust I have done in as far as was consistent with our arrangements here.

REMOVAL OF A DROPSICAL OVARIUM.

By GEORGE SOUTHAM,

Surgeon to the Salford and Pendleton Royal Dispensary, Manchester.

(For the *London Medical Gazette*.)

In the early part of last March, Mrs. H—, aged 37, of dark complexion, healthy appearance, and nervous temperament, was admitted under my care at the Dispensary, said to be suffering from dropsy. She stated that she had been the mother of six children, and formerly enjoyed good health. Two years and a half ago, when five months advanced in pregnancy, she felt something suddenly give way in the left iliac region, whilst lifting a washing mug, which caused her to faint, and afterwards to vomit about a table spoon-

ful of blood. She experienced no other inconvenience, excepting occasionally some shooting pains in the part after exertion, until within six weeks of her confinement, when the pain became so frequent that she was prevented attending to her ordinary household duties. After an exceedingly protracted labour, in which she was attended by a midwife, inflammation of the bowels and side followed, which required repeated leeching and blistering. Two months afterwards she felt a small tumor, above and to the left side of the pubis, but thought it was only "wind in the bowels." Shortly afterwards the abdomen began to increase in size, accompanied with pains, at first slight, but latterly very severe, and at times so acute as to confine her to her bed. By remedial means the abdominal enlargement has been frequently reduced, but never with any relief to the pains. When I first saw her she had the appearance of being six months advanced in pregnancy; she complained of pains in the abdomen, especially on the right side, which were increased when in the recumbent position, and prevented her altogether from lying on the left side. She had also a feeling of bearing down and frequent desire to pass urine, which often caused great pain; her bowels were constipated: catamenia regular, and general health apparently but little affected. On examining the abdomen, I felt a circumscribed tumor above the pubis, inclining rather to the left side: it was about the size of the foetal head at full term, and was very moveable under the integuments, but when drawn upwards caused pain in the left side.

There was distinct fluctuation, evidently from ascitic fluid, and percussion yielded a dull sound over the tumor. On examination per vaginam I found the os uteri perfectly healthy, and the uterus itself natural in size: the walls of the vagina were beginning to protrude externally; the tumor could not be felt, and apparently had no connection with the uterus. Being satisfied that the disease was ovarian, I informed the patient of the inefficiency of medicine in the cure of it, and that the only chance of its removal consisted in an operation, the dangers of which were fully explained to her. She appeared extremely desirous to be relieved of the tumor, which made life a

burden to her, and resolved, at whatever risk, to submit to the operation.

Accordingly, I requested my friends Drs. Radford and Clay to visit her, who after a careful examination concurred, with me as to the nature of the case, and the propriety of operating. Some delay took place in consequence of my colleagues at the Dispensary not sanctioning this measure. At length all obstacles were removed by the female placing herself under my care as a private patient.

Having fixed Friday, the 20th of Oct. for the operation, I directed her to avoid any violent exertion, also to abstain from stimulating food and drink for a few days. The oxgall disagreeing with her, the bowels were cleared out the preceding day with castor oil, which having acted freely, on the following morning an enema was considered unnecessary. I marked the abdomen in two places with nitrate of silver, and the temperature of the room was raised to 70°. About half-past twelve the patient was placed on a table in the recumbent posture, and in the presence of Drs. Radford and Clay, Messrs. Vaudrey, Slack, Carew, J. J. Southam, and Dorrington, surgeons, I commenced by making an incision through the skin from the right of the umbilicus, along the mesial line, to within three inches of the symphysis pubis, and after carefully dissecting through the different muscular layers, exposed the peritoneum. I punctured it half way between the umbilicus and pubis, on which a quantity of straw-coloured ascitic fluid began to escape. When upwards of four quarts had flowed, I made the opening large enough to admit my finger. Finding there were no obstacles likely to impede the further progress of the operation, I enlarged the wound above and below, with a probe-pointed bistoury, to the extent of nine inches, using my fingers as a director. The tumor was now fully exposed, and the omentum being firmly adherent to it at the upper part, was carefully dissected away. Mr. Slack prevented the intestines from escaping, which were very much distended with flatus, and extremely vascular. Dr. Clay raised the tumor whilst I passed my fingers behind the left broad ligament to the whole extent of which it was attached.

As the patient in this stage began

very sick, some difficulty was experienced in keeping the intestines from protruding round the pedicle. Instead, therefore, of using the ligature needle, I carefully made an opening with a scalpel through the centre of the ligament, at the same time protecting the viscera behind the tumor with my fingers previously introduced. Two ligatures were passed through the wound; the one near the uterus was easily tied, but the other broke, though it consisted of the strongest dentist's silk. The diseased mass was now removed by dividing the pedicle about an inch from the ligatures; the only hæmorrhage which followed came from the tumor, which being quickly removed, very little blood escaped into the abdominal cavity. The external integuments were immediately brought together, and after waiting a few minutes, during which the ascitic fluid was allowed to escape, the pedicle and omentum were examined, but there was not the least hæmorrhage.

The ligatures were tied on a knot and placed at the lower extremity of the wound, the edges of which were retained in juxtaposition by seven uninterrupted sutures and adhesive straps. Two long pads were placed on each side of the incision, and the whole secured by a broad bandage. During the whole operation, which the patient bore with great fortitude, not more than three ounces of blood were lost; and, with the exception of the delay occasioned by removing the ascitic fluid, which amounted to about fourteen pounds, it did not occupy many minutes. After being placed in bed, she was sick several times, complained of pain in the loins and left side; pulse 90, soft.

I ordered her gr. j. of Morphine in an ounce of Camphor Mixture, and to have nothing but toast-water, and that only in small quantities when thirsty.

Three hours after the operation.—Pulse 90, small; temperature of room 74°; not vomited since the draught; slept half an hour; surface of the body cold and moist; parted with flatus several times.

Half-past 6 P.M.—Pulse 95, soft and feeble; surface of the body comfortably warm and moist; temperature of room 73°; slept frequently for ten minutes

* Dr. Clay examined the opposite ovary, and found it healthy.

or a quarter of an hour at once; no vomiting; pains in the loins and left side very severe.

Half-past 10 P.M.—Visited with Dr. Clay and Mr. Carew. Pulse 106, feeble and small; cough rather troublesome; parted with a considerable quantity of flatus; vomited once since last visit; not slept; passed about a pint of pale straw-coloured urine without the use of the catheter.

Rep. Haust. Morph. gr. $\frac{3}{4}$ ds.

Half-past 12.—Pulse 110, small; complains of pain in the region of the stomach; vomited the draught; afterwards slept upwards of an hour, but has been sick twice since awaking; temperature of room 71°; ordered to keep it at 70°.

Habeat Morph. Acet. gr. j. in formâ pilulæ.

21st, 7 A.M.—Slept two hours after the pill; vomited several times within the last three hours; tongue white and moist; pulse 110, fuller; pain continues in the epigastrium and left side; abdomen distended, and rather tender on pressure; thirst and heat of skin increased; respiration free; no shivering; passed another pint of urine; flatulency continues.

Bled to 12 oz., which caused her to feel faint. To abstain from all kinds of fluids. When thirsty to rinse the mouth with water.

Half-past 11 A.M.—Pulse 120, soft; has still pain in the epigastrium and left side, but less severe than before bleeding; abdomen very much distended; passed urine and flatus, but had no motion; vomiting continues.

Habeat Enema Commune. Stat. Rep. Pilul. Morph. gr. $\frac{1}{2}$.

3 P.M.—No fecal matter returned with the injection, but it caused her to part with a considerable quantity of flatus, which has given her great relief, having been free from pain ever since; vomited immediately after the administration of the enema, but not since taking the pill; pulse 120, soft; surface of the body comfortably warm and moist; thirst troublesome; slept at short intervals.

To have a little ice occasionally.

10 P.M.—Vomited several times since last report; she thinks the ice increases it; free from pain; pulse 120, soft and small; abdomen much distended, but not painful on pressure. Examined

the wound, but found no protrusion of the bowels; indeed it had almost healed: but the ligatures were missing, having evidently been drawn into the abdomen by the distension and frequent vomiting.

To repeat the injection, and to have a rectum-tube passed when the flatulence is troublesome.

Rep. Pil. Morph. gr. j.

22d, 3 A.M.—Vomited the pill, and continues sick; no motion with the enema, but it has relieved the abdominal distension.

Rep. Pilul. To take the effervescing magnesia occasionally.

7 A.M.—Pulse 120, small and feeble; sickness continues, but not so frequent since she began with the effervescing draughts; passed urine freely; tympanitis continues; had no motion; still troubled with flatulency; countenance anxious; feels very faint at times.

To have a turpentine enema. Rep. Pil. Morph. gr. $\frac{1}{2}$. To take the effervescing magnesia every half hour, with ten drops of Sp. Am. Aromat. To have brandy and arrow-root in small quantities when fainting comes on.

1 P.M.—The injection not producing any effect, the nurse repeated it; what returned with the last was very offensive, but contained no faecal matter; pulse 125, feeble; not vomited since last visit; slept at intervals.

Repeat the turpentine enemata.

Half-past 6 P.M.—A small quantity of faecal matter came away with the last injection; not been sick since this morning; hungry.

To take a little panada.

Half-past 10 P.M.—Very low; countenance anxious, and eyes much sunk; pulse 140, thready; tongue beginning to assume a morbid redness at the edges, white and dry in the centre; had no evacuation; the abdomen still tympanitic; surface of the body comfortably warm and moist; no shivering; continues to pass urine without assistance; complains still of flatulence; wound healthy; removed four of the sutures.

R Ext. Col. Co. gr. v.; Hydr. Chlorid. gr. iij.; Mucilag. G. Acacia q. s. fiat pilul. ij.; St. Sumend. et rep. 3ta hor. si opus sit. Soda water ad libitum.

23d, 7 A.M.—Passed a comfortable

night, having slept soundly for several hours; only been sick once, which was after the second dose of pills; free from pain in the abdomen, which continues tympanitic; still troubled with flatulence, and complains of a burning heat and rising in the throat, as if she had been drinking turpentine. Tongue white, moist, and less red at the edges; pulse 130, soft and feeble; skin moist and warm; no shivering; passed urine freely; had an injection half an hour since, which has brought away a small quantity of feces; thinks her bowels will be moved shortly; if not in the course of an hour to have an enema of gruel containing 5 gt. Ol. Croton.

Continue the soda water.

11 A.M.—Still no evacuation.

Repr. Pil. Col. c. Cal.

3 P.M.—Vomited an hour after taking the pills; the heartburn very distressing; tongue dry; pulse very feeble, 120. Thinks she could take some castor oil in brandy and soda water.

Ordered half an ounce; if it remains, to be repeated every two hours until the bowels are acted upon.

10 P.M.—Had the bowels moved in an hour after taking the first dose of oil, and have been freely moved twice since; tongue cleaner and moist; pulse feeble, soft, 130; abdomen free from pain; she appears very restless, which, she says, is owing to the burning heat in her throat; no shivering; skin moist; been sick since last visit after taking some linseed tea, which she thought she could like. Taken a little beef-tea, which stayed.

Ordered soda-water and milk.

24th, 7 A.M.—Passed a restless night; been sick, which she attributes to the milk; complains still of the burning heat in the throat and stomach; tongue white and moist; has an extremely unpleasant taste in the mouth; no shivering; pulse 118, feeble and soft; countenance anxious; passed urine freely; and had one motion since three o'clock: complains of pain in the lower part of the abdomen, which shoots up towards the chest: feels sick, but has not vomited lately; the abdomen distended, especially at the lower part, but appears to be from flatus in the bowels; the wound has healed, except to the side and immediately below the umbilicus; removed the remaining sutures.

Omit the milk. Add a tea-spoonful of brandy to each dose of soda-water; rectum tube to be introduced, and afterwards to have an enema, consisting of four ounces of beef-tea.

11 A.M.—The beef-tea injection remained two hours, when she had a motion. The burning heat continues very distressing; vomited once since last visit, and still feels sick; at times pain in the abdomen. The pads were removed, a bandage placed over the plaisters, and a poultice of scalded bran ordered to be kept constantly applied.

To have iced jelly; continue the soda-water ad libitum.

Half-past 9 P.M.—Not been sick since this morning, and appears in every respect better: pulse 112. The jelly has relieved the burning heat in the throat.

25th, 7 A.M.—Passed a comfortable night, slept since ten o'clock without interruption; pulse soft, 112, still feeble; tongue moist, white, loaded at the base. The burning heat almost gone. Skin warm and moist; no coldness, or shivering; temperature 70°; urine rather thick, and after standing a short time deposited a sediment like brick-dust; less thirst; very anxious to be allowed a little tea, which was ordered; bowels moved once slightly.

To have some beef-tea and toast.

9 P.M.—Continues to improve; bowels moved freely once during the day; pulse 106, soft; not used the poultices to-day, having been free from pain in the abdomen; the temperature of room to be reduced to 65°.

26th, 12 A.M.—Was rather thirsty in the night, increased in consequence of being without soda-water; in other respects passed a good night, and slept soundly for several hours; had no pain since last visit; tongue cleaning, countenance improved; pulse 104, soft; passed urine freely; had a motion in the night, more consistent and healthy in appearance; not the least sickness; skin comfortably moist and warm; altogether very much improved; slight cough, which sometimes causes pain in the chest.

Half-past 8 P.M.—Has had some pain in the lower part of the abdomen, but the bran poultices have relieved it; both iliac regions are rather tender on pressure; not the least sickness; pulse soft, 110; says she feels herself much better. Having had no alvine evacua-

tion to-day, she was ordered a common injection, and, if the pain returns, to foment the abdomen, and apply poultices afterwards.

27th, half-past 7 A.M.—The fomentation and injection removed the pain from the lower part of the abdomen; passed a good night; bowels moved slightly in the night, the feces rather scybalous; tongue much cleaner; pulse soft, 106; passed urine freely; cough better; skin moist and warm; temperature 65; wound proceeding favourably.

Ordered—Oli. Ricini ʒss. in brandy and water. To have some weak mutton broth for dinner.

Half-past 8 P.M.—Not so well; complains of pricking pain in the left iliac region, which prevents her taking a deep inspiration; can bear pressure on the abdomen, which appears to relieve the pain, evidently owing to flatulence; pulse soft; tongue continues clean; temperature of room 65°.

Fomentation with camomile flowers and poppyheads. To have the rectum tube passed. Pil. Morph. Acet. gr. ʒ. st. sumend.

28th, 8 A.M.—Passed a comfortable night, having received immediate relief from the remedies prescribed; pulse 120, soft; hungry; able to lay on either side; parted with a deal of flatus during the night; countenance cheerful.

Diet to consist of veal broth, tea, jelly, and soda-water if thirsty.

29th, 10 A.M.—The flatulent pains returned suddenly in the night, which were relieved by the remedies ordered; much flatus passed after the introduction of the tube; pulse 125, soft, weak; tongue clean, but rather redder than natural, and papillæ at the end elevated; free from pain, but feels low; rather thirsty; passed urine freely in the night. Took some castor oil early this morning, which has not yet operated.

Ordered a common enema immediately. To continue the same diet.

30th, 10 A.M.—Appears much better; perspires freely; passed a good night; bowels moved three times yesterday; the evacuations rather scybalous; tongue clean and moist—still morbidly red; pulse 116. To have a light sago pudding for dinner in addition to veal broth.

31st, 10 A.M.—Passed a comfortable night; pulse 100. Took a dose of castor oil this morning, which has not yet operated.

8 P.M.—Complaining of pain in right side, increased on pressure; pulse 108, full; bowels been moved three times.

Appl. Hirudines, viij. part. affect.

Repr. Pil. Morph.

November 1st.—Pulse soft—morning 100, evening 110; feels rather low, but in other respects improved. Leeches relieved the pain and tenderness. Wound healthy, almost healed; bowels moved once; tongue clean, and more natural in colour.

2d.—Continues to improve. Pulse 100 in the morning, 110 in the evening, soft; tongue clean, and assuming its natural colour; bowels regular. Diet to-day consisted of sago pudding, veal broth, an egg, and dry toast.

4th.—Able to sit up; tongue clean, and perfectly natural in colour; can lie in any position, and says she feels comparatively well, suffering now only from debility; pulse 88 in the morning, 90 in the evening.

6th.—Wound not quite healed below the umbilicus; touched it with nitrate of silver. Sat up yesterday upwards of an hour. Took a mutton chop and half a glass of sherry wine for dinner, which agreed. Pulse 88.

9th.—Has gained strength considerably; able to walk about the room; wound quite healed.

12th.—Continues to proceed favourably.

Description of the Tumor.

The form of the tumor is nearly round, and rather flat, measuring about eight inches in diameter. It weighs four pounds, twelve ounces; and the ascitic fluid which accompanied it, fourteen pounds. The tumor is composed of solid matter and several cysts, which vary in size, giving it a lobulated appearance externally. The solid portion is most prevalent in the vicinity of the pedicle, which has a broad base. The natural structure of the ovary is entirely destroyed, the tumor affording an excellent specimen of cystic sarcoma.

REMARKS.—This case is interesting from several circumstances. It affords additional testimony in favour of a free incision into the abdominal parietes for the extraction of diseased ovaria. By the establishment of this practice, to-

gether with several valuable remarks on the operation, Dr. Clay has laid the profession under great obligations.*

The mobility of the tumor, and the large quantity of ascitic fluid which surrounded it, rendered it probable that it was comparatively free from adhesions, and attached by a long narrow pedicle; conditions which are essential for the success of the *minor operation*. This plan of Mr. Jeaffreson's consists in making a small incision, of one and a half or two inches in length, into the abdomen, through which the ovarian sac is punctured with a trocar, and when emptied of its contents drawn through the opening, its pedicle tied and separated†.

Had such an operation been adopted in my case, great difficulties would have occurred. After the evacuation of the ascitic fluid, cyst after cyst would have required puncturing, the adhesions could not have been removed with any degree of facility, the solid part of the tumor would have presented insurmountable obstacles to its extraction, whilst considerable difficulty must have been experienced in securing the pedicle (even if it could have been drawn through the opening), owing to its thick, broad, and highly vascular condition.

On this subject Mr. Aston Key says, that the minor operation, "at first view, appears to be the safest and easier operation, requiring a smaller incision of the parietes of the abdomen, and exposing, in a much less degree, the viscera to the existing causes of inflammation. These advantages, however, are more than counterbalanced by the difficulty of manipulation which the operator experiences in getting a large collapsed mass through a small parietal incision, and in reaching the peduncle of the cyst so as to secure it by ligature. The larger incision does not probably expose the patient to a greater chance of inflammation than a smaller one; and it has the incalculable advantage of giving free access to the tumor, and facilitating its extraction from the abdominal cavity without violence. I look on the absence of all undue forcible manipulation as the main recommendation which this operation possesses‡."

The major operation does not consist

* Medical Times, 1842-3.

† Trans. Prov. Association, Vol. 5.

‡ Guy's Hospital Reports, Oct. 1843.

in a direct incision from ensiform cartilage to pubis, as Dr. Bird appears to have inferred, but in making an opening proportionate to the size of the solid parts of the tumor; and, when the disease is extensive, and wholly or in part fluid, reducing it by paracentesis either previously to, or during the operation.

An exploratory incision midway between the umbilicus and pubis is very necessary at the commencement of the operation, as in this position we are less likely to encounter adhesions, which are more frequent near to the umbilicus. When the tumor is of great magnitude, adhesions to the abdominal parietes are generally found above as well as in the vicinity of the umbilicus, except when it is overlapped by the omentum itself adhering.

With respect to the treatment of the case, it will be seen from the report that, for the first four days, the issue was very doubtful; and had it not been for the timely application of the lancet, and the free administration of morphine, in all probability peritonitis would have ensued, which the vascular condition of the peritoneum at the time of the operation evidently indicated. Flatulency and nausea proved most troublesome symptoms.

The rapidity with which the peritoneum healed deserves notice: in thirty-six hours after the operation it appeared firmly united through the whole length of the incision.

Not the least important feature in the case, which is worthy the attention of operators, consists in the retraction of the ends of the ligatures into the abdomen. In one of Mr. Walne's cases I find a similar accident occurred, which was also not attended with any unfavourable result, the ends of the ligatures reappearing at the lower extremity of the wound, before it had entirely healed (*Med. Gaz.* p. 437, vol. i. 1842.) The reader will no doubt be equally surprised to hear, as I was to find, that they had disappeared; for at least five inches of the cord were left external to the wound; besides the precaution being adopted of tying them on a knot, and placing a broad strap of adhesive plaster over them to retain them in their situation. This accident was evidently owing to the tympanitic distension of the abdomen, and the

motion of the parts from constant vomiting, whilst the adhesive powers of the plaster were destroyed by the oozing of ascitic fluid through the wound immediately after the operation.

This circumstance is an additional proof that the peritoneum is not so susceptible of inflammation from irritation as many have supposed.

Whether the ligatures will become encysted, or, what is more probable, they will ultimately be discharged by means of abscess, it is at present difficult to prognosticate. If any peculiarities occur in the after progress of the case, I shall feel it my duty to impart them to the profession.

[To be continued.]

ON THE STATISTICS OF FEVER IN ST. THOMAS'S HOSPITAL,

WITH REFERENCE TO TREATMENT.

By H. BURTON, M.D.

(For the *London Medical Gazette*.)

IF the importance of any branch of medical study be estimated by the works which have been written concerning its objects, and by the labour which has been bestowed on their investigation, few are more important than fever; but, notwithstanding the time which has been expended in collecting facts relating to it, and the ingenuity displayed in constructing theories, more precise data are yet wanting to insure a uniformity of results under conditions of disease apparently similar, and to check, in the language of Sir Alexander Crichton, "those extraordinary changes of opinion and innovations in practice, which have succeeded each other so rapidly during the last fifty years in regard to the doctrine and cure of continued fever of an adynamic character." (*Commentaries*, London, 1842.) Having been often perplexed by contradictory precepts relating to the treatment of fever, and by what appeared to me unwarranted preference for particular therapeutic methods, I was lately induced to undertake the task of collating the results of six years' experience of the fever which usually prevails in this metropolis, from my own practice at St. Thomas's Hospital; and with the

hope that the conclusions may prove interesting to others engaged in making analogous inquiries, I offer them to the public through the medium of the MEDICAL GAZETTE. In the arrangement of data I have derived several useful suggestions from the valuable "Reports on the St. John's Fever and Lock Hospitals in Limerick," by Dr. W. J. Geary, published in the Dublin Medical Journal, Vols. XI. and XII.; and am happy to acknowledge myself indebted to this Report, as well as to

the "Treatise on Fever," by Dr. S. Smith, (London, 1830,) for the means of comparing the average results noticed in the present communication. The fever to which my remarks apply was, in the years 1837 and 1838, epidemic in several districts of the metropolis, and between the spring of the former year and Midsummer 1843, 354 patients, including three in a moribund state, have been placed with this disease under my care, at the periods noted in the following table.

TABLE I.

ADMITTED.									DIED.							Monthly ratio of deaths to cures.	
Months.	1837	1838	1839	1840	1841	1842	1843	Total.	1837	1838	1839	1840	1841	1842	1843		Total.

Annual average mortality.	10 $\frac{1}{3}$	13 $\frac{2}{3}$	6 $\frac{2}{3}$	12	9 $\frac{1}{2}$	6	10	10 $\frac{4}{5}$	1	1	1	1	1	1	1	1	1

No cases of scarlet fever, measles, erysipelas, or small-pox, are enumerated in the above table, nor are there any cases of simple gastric fever, or

acute inflammatory disease, purposely included, excepting such as were complicated with cerebral innervation, or the characteristic stupor of typhus, and extreme prostration; but all were conceived to be either analogous to the continued fevers described by Dr. Huxham as putrid, petechial, and slow nervous fever; as synochus, contagious and malignant, by Dr. Willan and other eminent authors; or, to that adverted to by my friend and colleague, Dr. Robert Williams, in his *Elements of Medicine*, pp. 25 and 27, as simple continued fever, peculiar to this country, under the name of typhus, "caused by the agency of a typhoid poison." But although the combination of symptoms observed in the cases above enumerated was for the most part the same in all, yet there was not a perfect identity between them, for many differed either in respect of the virulence of the febrile poison, or some peculiarity about the previous condition and circumstances of the patient subjected to its action; there was nevertheless a sufficiently near correspondence between the principal features of the cases to entitle them to be considered examples of the same disease. It is not an object of this communication to give a detailed account of fever; but the reader should be informed, with relation to the influence of residence, and the previous condition and circumstances of the patients over the results of treatment, that they were for the most part servants, workmen, exposed to the ordinary hardships of their respective occupations, and others in a state of comparative destitution, inhabitants chiefly of the crowded districts of Southwark, or its immediate neighbourhood, where neglect of cleanliness about their abodes and persons, want, poverty, and fatigue, in conjunction with other depressing causes, tended to engender and diffuse fever of an adynamic character.

A short history of each case was usually obtained on the days of admission either from the patient or his friends, and the following analysis of the most remarkable symptoms noticed in 66 cases will give a tolerably accurate idea of their proportional occurrence in these as well as in the majority of the 354 cases enumerated in table No. I.

Analysis of Symptoms in 66 Cases of Fever admitted during the first five months of 1838.

Great prostration and inability to walk on the day of admission in . . .	31
Ordinary febrile prostration in . . .	35
Consciousness and ability to answer questions rationally when roused by a loud voice, but constant drowsiness and partial deafness, in . . .	56
Insensibility or delirium in . . .	10
Redness in conjunctiva remarkable in . . .	21
Headache in . . .	41
Morbid heat of head, or surface of the body, in . . .	54
Cold feet in . . .	9
Rashes or petechiæ in . . .	36
Radial pulse soft and regular, not small and weak, in . . .	14
Radial pulse very weak, small and regular, with a proportionately weak cardiac action, in . . .	46
Pulsations 112 to 130, usually 120, in . . .	50
Pulsations below 100, including 5 under 70, in . . .	16
Irregularity of radial pulse in . . .	3
Anorexia, more or less pronounced, in . . .	66
Tongue moist and white in . . .	29
Tongue dry or clammy, and brown in its centre, usually clean at its sides, in . . .	30
Abdominal tenderness on pressure in . . .	19
Diarrhœa in . . .	1
Costiveness in . . .	14
Tympanitis in . . .	0
Inspirations remarkably frequent in . . .	15
Cough in . . .	40
Dull sound on percussion over the chest, with indistinct vesicular murmur, in . . .	48
Sore-throat and hoarseness in . . .	3

No history of the accession of the symptoms is here required, but in reference to the duration of fever and its decline, it is proper to remark, that in no case was any sudden crisis observed; the disease subsided gradually, and its subsidence was marked in particular by an improving appetite, a cleaning of the tongue, and retardation of the pulse; the skin began to resume its ordinary temperature, the petechiæ or macule to fade, and the fulness of the features to be succeeded by pallor and contraction. As soon as these signs of amendment were unequivocally pronounced by a craving for more food, the patients were put upon a meat diet, and throughout the last six years and a half the immunity from any serious relapse was remarkable, particularly during the years 1837 and 1838. The few relapses which did occur were observed

chiefly among patients in whom symptoms referrible to the abdominal viscera had predominated, but no patient died in consequence of the return of fever after having been put upon a meat diet. In almost all the severe cases the brain, heart, and lungs, seemed to be during life the principal organs affected by the "typhoid poison," and in bodies which were examined post-mortem they were found to have been almost invariably more or less implicated; the heart was usually flabby, the lungs and brain congested, as well as in some cases the seat of organic lesions; the spleen gorged with blood, and easily broken down; the intestines sometimes ulcerated; but the alimentary canal was not observed to be so frequently diseased in the bodies examined at St. Thomas's between the years 1837 and 1843, as they seem to have been at Paris be-

tween the years 1820 and 1827, according to M. Andral's statement. (*Maladies de l'Abdomen*, t. i. p. 497.)

It is always more easy to recognize resemblances than to detect differences, and I accordingly feel more confident that the fevers enumerated in the foregoing table closely resembled one another, than that they did not differ in any material respect, so as to render them dissimilar diseases; and the same remarks may be applied to the fevers noticed in other statistical inquiries. Assuming, however, that my cases were examples of a similar disease, and strictly analogous to those noticed in other localities, the following and preceding average results of treatment lead to the inference that the mortality from fever varies very considerably at different periods from causes which act independent of locality. Thus:—

TABLE II.

At Limerick in 1817-18, the mean annual mortality among	4062 patients was	1 in $13\frac{1}{2}$.
“ “ 1819, “ “ “ “ “ “	3053	“ 1 in $18\frac{1}{4}$.
“ “ 1836, “ “ “ “ “ “	3206	“ 1 in 15.
At Glasgow 1836, “ “ “ “ “ “	1258	“ 1 in 10.
London Fever Hospital in 1825, 1826, 1827, 1828,	2537	“ 1 in $6\frac{6}{10}$.
Milan (Sir C. Morgan) in 1812, 1813, 1814, about	300	“ 1 in $8\frac{1}{2}$.
Hospital Ship Grampus, January 1831, to April	73	“ 1 in $7\frac{3}{10}$.
St. Thomas's Hospital, 1837 to June 1843, “	354	“ 1 in $10\frac{3}{8}$.

The variations observed in the rates of mortality represented above probably depend on many causes, some of which originate within, others external to the body, and operate in conjunction with the febrile virus; such as the existence of organic disease previous to the accession of fever; age, sex, day of fever on which treatment was commenced, and season of the year, among other modifying causes referrible to the usual condition and circumstances of the patient.

For the sake of information, therefore, I propose to inquire into the influence of these causes over the results of my own practice; and secondly, to compare these results with those collected from other sources.

Seasons.—Few circumstances appear to exert a greater or more universal influence over the results of treatment in fatal cases than the changes which are perpetually taking place among the components of the atmosphere, and due to the diurnal and annual motions of the earth, on which the seasons depend; but, by what particular atmospheric agent or combination of agents the variable rates of mortality are principally caused is not very obvious,

although our sensations are affected more frequently and unequivocally by changes in the degrees of heat and moisture than by any other agency; and the joint influence of cold and wet weather is usually most productive of disease, independent of any other manifestly vitiated condition of the air arising from the presence of miasmata, poisonous gases, or extraordinary states of rarity or density.

The combined influence of atmospheric agents over the mortality from fever at different seasons is exhibited in the following table.

TABLE III.

Quarters of Years.	Number of cases admitted.	Number of Deaths.	Average quarterly mortality.
First quarter	88	12	1 in $7\frac{1}{3}$.
Second quarter	86	5	1 in $17\frac{2}{3}$.
Third quarter	74	4	1 in $18\frac{1}{2}$.
Fourth quarter	86	12	1 in $7\frac{1}{8}$.

The disparity between the rates of mortality at different seasons is very remarkable, and the results above exhibited show distinctly that a larger proportion of patients died from fever

during the coldest seasons than the hottest of the last six years. These conclusions are generalized by the results of treatment published in the 3d and 4th "Reports of the Registrar-General of Deaths from Typhus in the Metropolis during the Years 1838, 1839, 1840, and 1841;" also by the remarks of Dr. R. Knox, published in the MED. GAZ. for Aug. 1843, p. 771, on the applications to the Fever Board at Edinburgh for the years from 1833 to 1838, and in particular by the instructive Report, already noticed, by Dr. Geary, who states the mortality at Limerick to have been during the two hottest quarters as 1 in 15 $\frac{1}{2}$, and during the two coldest as 1 in 11 $\frac{3}{4}$ patients. The average mortality from fever is sometimes very high, but

it seldom continues the same, and is generally much less annually than that which results from mixed diseases, chronic as well as acute, treated by physicians in hospitals, whereas the average mortality from mixed diseases remains nearly the same, and does not vary to any remarkable extent with the seasons. A rough estimate of the comparative danger to be apprehended from the two classes may be made by contrasting the mortality from typhus only, with that from all other diseases, including typhus, treated by the physicians in St. Thomas's during equal and corresponding periods, as exhibited in the following table, No. IV. shewing the aggregate number of deaths and admissions of patients with all diseases.

TABLE IV.

DEATHS.							ADMISSIONS.						Monthly Totals	Average monthly mortality
Months.	1837	1838	1839	1840	1841	1842	1837	1838	1839	1840	1841	1842		
Jan. .	18	26	13	31	15	13	121	131	141	117	99	115	724	1 in $6\frac{2}{13}$
Feb. .	15	25	17	17	23	15	118	122	103	117	106	114	680	1 in $6\frac{1}{14}$
March	16	20	10	12	19	12	89	121	122	133	150	141	756	1 in $8\frac{1}{2}$
April .	13	18	13	17	11	11	83	100	118	135	122	117	709	1 in $8\frac{1}{4}$
May .	21	15	12	14	17	9	88	147	102	126	109	123	766	1 in $8\frac{3}{4}$
June .	21	14	19	10	6	13	83	103	102	116	125	148	711	1 in $8\frac{3}{4}$
July .	19	11	16	23	13	14	96	124	132	139	119	128	801	1 in $8\frac{1}{8}$
Aug. .	17	18	13	17	10	16	91	140	144	109	107	153	768	1 in $8\frac{3}{8}$
Sept. .	16	27	12	22	14	14	105	118	121	122	138	126	744	1 in $7\frac{9}{13}$
Oct. .	18	11	12	15	13	20	89	138	124	131	94	107	773	1 in $8\frac{11}{19}$
Nov. .	26	14	10	20	16	18	104	114	128	99	99	147	695	1 in $6\frac{1}{4}$
Dec. .	26	14	14	15	15	10	94	116	105	118	108	90	673	1 in $7\frac{5}{14}$
Annual totals	226	213	161	213	172	165	1150	1437	1451	1461	1388	1496	8800	
Annual average mortality	1	1	1	1	1	1	$6\frac{5}{10}$	$6\frac{3}{10}$	9	$6\frac{3}{10}$	$8\frac{3}{10}$	$9\frac{1}{2}$		Mean annual average mortality 1 in $7\frac{3}{4}$.

In this arrangement, the mean average mortality among 8800 patients for the last six years is shewn to have been 1 in $7\frac{3}{4}$; again, the average annual mortality in 1819 among 1008 patients placed under the three physicians of the hospital, was 1 in $7\frac{3}{4}$; and in 1820, among 1121 patients, 1 in $9\frac{1}{2}$, or the same rate as in 1842: hence there is good reason to believe that no material or constant difference in the rates of mortality has occurred at that institution during the last 23 years among the physicians' patients.

Sex.—Having adduced evidence of the unequal influence exerted by the seasons over the mortality from fever, let me next inquire briefly into the influence of sex, without reference to either season or age, as represented by the mortality which occurred among the total number of patients, 354, enumerated in Table No. 1. Of this number, upon reference to my notes, the admissions and deaths of the two sexes took place in the following proportion:—

TABLE V.

Sex.	Admitted.	Died.	Average Mortality.	Difference.
Females	145	11	1 in $13\frac{2}{11}$	5
Males	209	24	1 in $8\frac{3}{4}$	

The rate of mortality, therefore, during corresponding periods was considerably greater among the male than female patients. A corresponding difference of 5, omitting fractions, was observed between the proportional mortality of the two sexes at Glasgow in 1836, by Dr. Cowan (Dublin Medical Journal, vol. xii. p. 99, &c.) where, among 1258 patients, 1 female died out of every $11\frac{1}{2}$ admitted into hospital, and 1 male out of $6\frac{1}{2}$. But the difference observed by Dr. Cowan and myself as regards the influence of sex was not noticed by Dr. W. J. Geary, at Limerick, in the year 1835, where the proportional mortality among females was 1 in $13\frac{1}{2}$, and among males 1 in 14. The influence of sex, therefore, is not invariably the same over the mortality from fever, and Dr. Cowan states, that although at almost all periods of life the deaths among males exceed those among

females, yet under 15 years they are equal in the two sexes.

Age.—The ages of 311 out of the 354 patients enumerated in Table No. 1, were ascertained and recorded whilst in hospital; and the subjoined table shews that age, in mixed cases, and at all seasons, exerts a marked influence over the mortality from fever.

TABLE No. VI.
Shewing the relation between the ages, recoveries, and deaths, in 311 cases of either sex.

Ages	Number of cases	Number of recoveries	Number of deaths	Total		
				Over	Known	Unknown
5	20	19	1	13	311	43
10	31	30	1	6	311	43
15	66	65	1	1	311	43
20	68	61	7	—	284	34
25	35	32	3	—	284	34
30	20	18	2	—	284	34
35	17	16	1	—	284	34
40	16	14	2	—	284	34
45	13	11	2	—	284	34
50	5	4	1	—	284	34
55	6	2	4	—	284	34
60	1	—	1	—	284	34
Grand Total	354	319	35	—	—	—

There is reason to believe, from the above statement, that the youngest have the best chance of surviving, and persons under thirty years are more susceptible of fever than those above that age; but that the proportional mortality among them is less than among those who have attained a more advanced age: thus, among 240 patients who had fever under or at 30 years, 15 patients died, or 1 in 16; but among 71 patients who were admitted during the same interval of six years,

above the age of 30 years, 12 died, or 1 in 6. The chances of recovery, therefore, from fever, is $2\frac{2}{3}$ greater among patients under 30 years, than between that age and 60 years. A similar conclusion, deduced from a much more extended series of cases, has been expressed by Dr. Cowan and Dr. W. Geary, and although our ratios differ, yet they are near enough to shew that the influence of age generally over the mortality from fever corresponded in Limerick, Glasgow, and Southwark. Thus at Limerick the annual proportion was 1 in 22 under and at 30 years; and 1 in $4\frac{1}{2}$ between 30 and 71 years. At Glasgow, it was 1 in 12 under 30 years, and 1 in 4 above that age.

[To be continued.]

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 172.]

PART II.

IT has been already stated in an early part of this memoir that an exception or two existed to the singular law, that in all mammals there are but seven cervical vertebræ. Some cetacea seem to have but six; the sloth has eight or nine. Now, are these supernumerary vertebræ in the sloth, cervical vertebræ properly so called; or are they dorsal; or may they not belong to a group of vertebræ intermediate of both, and such as the seventh cervical vertebra appears to be in man? This difficult question has been frequently examined, and perhaps most recently by M. de Blainville, whose opinion is as follows:—

I quote from the fifth Vol. of his great work on "Osteographie:" the observations have a reference merely to the ai or three-toed sloth (*Bradypus Tridact.*, L.) for all sloths do not present the peculiarities in the cervical region of the spinal column about to be discussed.

"In the vertebral column there are but 41 vertebræ, instead of 47, as in the two-toed *Bradypus*, of which nine or eight are cervical, and 24 dorsal. The cervical vertebræ of the ai may be

characterized by their having their bodies cut obliquely at both extremities; they are all nearly of the same diameter, and their processes are generally less distinctly marked than in the unau. The atlas, which is the largest, has an inferior tubercle, but no superior; the spinous process of the axis is also less than in the unau. The five following intermediate vertebræ present some slight shades of difference: the eighth resembles the seventh, being merely a little larger in all its parts; but the transverse process is bifid profoundly, the inferior lobe narrower and turned forwards, and the base pierced with a larger foramen than in the preceding.

"The ninth has finally more of a dorsal character, its spinous process being higher, larger, and sloped more backwards. The transverse processes are perforated at their base by a very small opening; they are simple, but much larger, thicker, obtuse, and curved downwards. On examining them attentively, as well on this ninth vertebra as likewise on the eighth, we find that the terminal third (of these transverse processes) is separated from the rest by a very close articular surface, which has induced Mr. Bell to view this epiphysis as a rudiment of ribs analogous to the asternal ribs of birds; an opinion we are very far from adopting."

In a lengthened note which, as the subject is interesting, I have taken the liberty to subjoin, M. de Blainville continues his examination of the singular exception, seeming or real, which the neck of the three-toed sloth presents to the great numerical law pervading all mammals.

"The dorsal vertebræ are sixteen in number; the lumbar three: these differ but slightly from their analogous bones in the unau.

"The sacrum appears to be formed of only six vertebræ, the transverse processes of the first not always reaching the bones of the ileum: on the other hand, the last sacral vertebra appears to be moveable, but whose transverse process, very long, is united to those of the preceding one, and to the ischium.*"

* Philosophie or transcendental anatomy will find no difficulty in explaining, up to a certain point at least, most of the facts described in the preceding memoir. M. Carus, for example, who has embodied most of the laws of transcendental anatomy in his "*Traité Élémentaire d'Anatomie Comparée*," would merely remind his readers

Setting aside, then, the more extended considerations connected with the transcendental anatomy of the vertebral column and ribs in the whole series of the vertebrata, as being inappropriate here, and limiting our view to the mammalia, and more especially to what structures we find in the sloth (*Bradypus Trid.*), and in man, it appears:—

1st. That as regards man, there are seven cervical vertebræ, divisible into three groups, viz. :—

		Man.	Al.
		1st	1st.
Cervical vertebræ	1st Group	2d	2d.
		3	3.
	2d Group	4	4.
		5	5.
		6	6.
		7th.	
	3d Group	7th	8th.
		8th.	
		9th.	

That in respect to the five inferior ones (leaving out all consideration for the present of the first and second, as being peculiar and specific) at birth they are found to present three great centres of ossification, viz. a middle portion, which forms a *portion* of that part of the vertebra which the descriptive anatomist calls the body of the vertebra, and two lateral portions, including each of them a base or pedicle,

that each "protovertebral arch" is divided primordially into four parts on each side; two tergal, one superior, the other inferior; and two sternal, the one superior, the other inferior. The cervical ribs, then, are merely the proto-vertebral arches of the cervical vertebra. The tergal portions of these arches are the arches which enclose the vertebral arteries; I presume he also includes the human cervical ribs, although he does not say so; and the sternal portions are the scapula and clavicle. These views, no doubt, are ingenious and profound; they belong to Goethe, and may be traced to Newton; but the physiologist, pursuing his inquiries into human physiology, ought, I think, always to endeavour to recollect that they are merely theoretical, and essentially abstract: correct enough, no doubt, but well adapted to mislead and misdirect the incautious. This with great deference seems to me the danger: these views are true in the abstract, but not so in the practical application; they confound the "creative idea" and the "results" or manifestation; they lead persons to suppose matters capable of intuitive evidence which can only be made the subject of abstract speculation. But it is surprising and pleasing to observe, how beautifully, by keeping in view the sublime abstract doctrines of Goethe, individual facts receive illustration and explanation. The subdivision of each rib, for example, and its cartilages, into distinct elementary portions, germs, or elements, each distinct and dependent, and each following its own laws of development, is a fact, proving the "creative idea" to have been essentially complex, yet simple, sublime, all foreseeing.

entering largely into the composition of the so-called body of the vertebra, and forming ultimately the whole of the processes.

2d. That the transverse processes, being those only which here require being considered, present probably in all the vertebræ, when present, a double root presenting various stages of development: the posterior root being early ossified in the human cervical vertebræ, whilst the anterior are generally cartilaginous at birth and slender, compared with the posterior roots.

3d. That these anterior roots of the transverse process contain the elements of at least two structures; viz. a process which in the intermediate cervical vertebræ extending outwards unites with the posterior root, and so forms the foramen for the vertebral artery; and a shorter and stronger part, which ultimately becomes the *facet* for the articulation of another element; that is, the head of the rib.

4th. That in respect to the dorsal vertebræ the transverse processes have equally two roots, an anterior and posterior, but the development of the anterior root is limited to the formation of the articular facet.

The transverse processes of the seventh cervical vertebræ merit especial notice, because they absolutely combine, in more senses than one, the characters of both regions, viz. cervical and dorsal.

1st. They resemble the cervical in having the anterior root not unfrequently very perfectly developed, and thus forming a foramen, through which, however, I never heard that the vertebral artery does pass, although this is the use assigned for the foramen; but this anterior process may be extremely small, or not developed, and then the foramen may be completed in another way, viz. :—

2d. By the presence of a separate bone or rib, resting by its proximal extremity on the root of the pedicle or facet, and either extending beyond the extremity of the posterior root so as to form a rib, or uniting with the transverse process, and often mistaken for the anterior root alone: or,

3d. The rib may be present, and the anterior root too, shewing that they are independent structures, and not convertible into each other.

As regards the genus *Bradypus*; for a reason unknown to us, but probably connected with the extinct or fossil mammal (provided we can call them mammalia), nature has departed from a law at first thought to be universal, and multiplied the number of the cervical vertebræ in certain species of the sloth to eight or nine; which vertebræ probably form a distinct group, analogous, however, to the seventh in man: they carry ribs, which are more rudimentary than in man, being limited in their development to the tubercle and a portion of the body, whereas in man the cervical ribs have a head and neck, tubercle and body, complete; and that such an appearance has additional analogies with the classes birds and reptiles, but that for the present the connecting links are unknown.

In respect to the region to which these supernumerary vertebræ may be supposed to belong, they must still be considered as cervical; the circumstance of their carrying a rib not being a sufficient reason for considering them as thoracic or dorsal. If we admit it as sufficient we must then change the nomenclature of the human skeleton, and say that man has only six cervical vertebræ, inasmuch as the seventh so-called cervical carries a rib, probably quite as regularly so, as the eighth and ninth in the sloth.

MIDWIFERY CASE.

To the Editor of the Medical Gazette.

SIR,

I HOPE the case stated below may not be unworthy of your columns; it is one which is probably of common occurrence to more experienced practitioners than myself, but as it made some impression on me, I send it you, that it may benefit others in like manner.—I am, sir,

Your obedient servant,

J. H. STALLARD,
Surgeon.

New Street, Leicester,
Nov. 1843.

Nov. 1st, 8 P.M.—I was sent for to Mrs. Morton, who had been in labour some time of her sixth child. About two weeks ago she had flooding to a considerable amount, and having

ceased, it returned with increased violence last night. Since this time she has had constant flooding. She states that she had pains four days ago, and that her waters broke at that time. She is now pale and debilitated; has no uterine pain, and the hæmorrhage is considerable. The os uteri is dilated to a considerable extent, and the head is felt through a thick rough substance resembling the placenta. I now gave ʒss. of the ergot, in the form of decoction, and repeated the dose in twenty minutes, no effect having followed the first dose. This rather increased than diminished the hæmorrhage, and no uterine pains were produced. I now sent for my father, told him that I suspected "*placenta prævia*," as the hæmorrhage was so considerable, and the mass presenting much resembled it as to the touch. Having examined, he pronounced it to be the "*placenta sure enough*;" and as the woman was faint, we resolved to proceed at once. On tearing through the presenting substance, we found it to be composed of membranes highly thickened, and when broken through a large quantity of liquor amnii escaped. That this was in fact liquor amnii was ascertained only by inspection, as we were quite convinced that it was the placenta which was felt. The hæmorrhage now stopped, and the labour proceeded as well as the weakly state of the woman would allow.

The error of diagnosis was here caused—1st, by the statement of the woman that the membranes were already ruptured; 2dly, by the hæmorrhage before and during labour; and lastly, by the peculiar feel of the thickened membranes. The point of practice which this case inculcates is, to ascertain that the fluid poured out by the rupture of the membrane be not blood; for I conceive that great experience in these cases, and in *placenta prævia*, will be required before we can tell the difference by the *character* of the rush of fluid, at least with tolerable certainty. It will be evident to what unnecessary risks we should have subjected the woman, if we had proceeded to turn without having surely ascertained the necessity for so doing.

CHOLERA.

Copy of a Letter addressed to the Medical Board of Bengal, by G. C. RANKIN, Esq. Assistant-Surgeon to the Calcutta General Hospital, and dated Calcutta, 15th September, 1843.

SIR,

CONTINUED and careful observation, with such opportunities as the General Hospital affords, and the perusal, within the last few days, of the most recent notes on cholera, having so fully corroborated my impression with regard to the nature and seat of that disease as to leave no doubt on my mind, I shall probably feel it a duty, ere long, to devote a few pages to the subject, for the purpose of laying it before the profession at large.

In the meantime, having discussed the matter freely with some twenty medical gentlemen of Her Majesty's and the Hon. Company's Service, within the past eighteen months, without encountering any important objection, I deem it expedient, for the information of the Medical Board, briefly to state my conviction,—

1st. That it is in the absorbent system the seat of the disease must be sought.

2d. That obstruction, from whatever cause, takes place in the absorbents, interrupting the passage of the chyle into the circulation.

3d. That the chyle so interrupted in its progress to the receptaculum chyli and thoracic duct, is regurgitated into the digestive canal; and

4th. That the so-called "rice-water" fluid ejected from the stomach and bowels is neither more nor less than the chyle so regurgitated, and which ought to have passed into the circulation, as well for the purposes of nutrition, &c. as to maintain the blood in a sufficiently dilute state for capillary circulation, and the sudden interruption of which necessary supply fully accounts for all the phenomena of cholera—for the almost immediate and rapid collapse, as well as for the subsequent capillary obstruction so conspicuous in those lingering cases where so much depends on the cautious attention and judgment of the physician.

I will not here anticipate my (possible) *brochure* on this subject, farther than by a general reference to reports of dissections, and particularly the very

excellent statement, by Dr. Budd and Mr. Busk, of the Dreadnought cases; to the article "Cholera," in Dr. Tweedie's Library of Medicine; and to my own Case-book, and post-mortem notes for twenty months past: but a knowledge of the seat of the disease being the first and most important step towards successful treatment, I trust the Medical Board will regard this as a matter of sufficient general interest to warrant their submitting it to the medical department of this Presidency, with the view to elicit such objections (if they exist) as may not have presented themselves to me.

I have the honour to be, sir,

Your most obedient servant,

G. RANKIN,

Assistant-Surgeon, Gen. Hospital.

*J. Forsyth, Esq. Official Secretary,
Medical Board, Calcutta.*

CASE OF ACUTE BRONCHITIS.

COMMUNICATED

BY DR. HASTINGS.

(For the Medical Gazette.)

CHARLES PERRY, aged 24, by trade a carrier, was born and always resided at Wickham Bishops, in Essex. His parents were long-lived and healthy; his hair red, complexion florid, and skin fine and clear. His general health was good until last February, when he sought relief for an attack of acute bronchitis. The prominent symptoms were then severe cough, frothy expectoration, difficulty of breathing, and considerable fever. This state of things soon subsided, but the difficulty of breathing and cough recurred, accompanied with expectoration of a well-marked purulent character, and nocturnal perspirations, and followed by great emaciation and consequent debility. On applying the ear to the right side of the chest anteriorly, pectoriloquy and a gurgling rale were perceptible. Various treatments were pursued until April, when, as improvement had not manifested itself, he withdrew from my care, and placed himself under Dr. Baker, of Maldon, who endeavoured to gain admission for him into the Colchester Hospital, but failed, in consequence of his disease being supposed to be pulmonary consumption in the last stage. Dr. Baker treated him for consumption, until an attack of hæmoptysis in July

led him again to consult me. His condition was now more feeble than at his former visit. Under the use of the acetate of lead and opium the spitting of blood shortly disappeared, leaving all the previous symptoms of pulmonary consumption unmitigated. Being unacquainted with any treatment possessing the power of stopping the ravages of this disease, I determined to try naphtha, not with any expectation that a beneficial result would ensue, for I must add, that I had not the slightest faith in its (alleged) powers in this formidable malady. On the 3d of August, then, I prescribed the following:—

R Naphth. Rect. ʒj. ; Liq. Op. Sed. ʒij. M.

of which he took fifteen drops three times a day in a little water. The naphtha was persevered in for about two months, when he reported himself well, and resumed his employment of carrier between Witham and London, having gained about two stone in weight during the treatment. The first remarkable change was a disappearance of the nocturnal perspirations, which never returned after taking a few doses of naphtha. The cough and expectoration gradually yielded, and the only difference between his present and previous condition before the attack in February, was that his breath was rather short after considerable bodily exertion.

(Signed)

A. G. PROCTOR,
Surgeon.

Witham, Essex.
Oct. 21, 1843.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur tue à abrégé.”—D'ALEMBERT.

Medico-Chirurgical Transactions, published by the Royal Medical and Chirurgical Society of London. 2d Series, Vol. VIII. Longman and Co. 1843.

[Concluded from page 181.]

Some Account of an Epidemic which prevailed at Tcheran, in the months of January and February 1842. By C. W. BELL, M.D. attached to H. B. M.'s Mission at the Court of Persia.

THE disease above alluded to consisted of pain in the head, spasms of the limbs, numbness, and more or less of

paralysis; attended with fits, in which there were convulsions and stertor. Bleeding and purging were adopted in the first instance, and followed up by assafoetida, iron, and similar remedies.

On the Nature of the Ossification of Encysted Tumors. By JOHN DALRYMPLE, Esq. Surgeon to the London Ophthalmic Hospital.

MR. DALRYMPLE removed a small tumor from beneath the tarsal cartilage of the upper eyelid in a middle-aged man, which contained apparently earthy or bony deposit. Upon examining it with the microscope, the concentric layers were found to be composed entirely of epithelium scales, closely connected together, but without any amorphous earthy deposit, the whole being composed of this epithelium.

On the Anatomical Characters of some Adventitious Structures, being an attempt to point out the relation between the microscopic characters and those which are discernible by the naked eye. By THOMAS HODGKIN, M.D.

THIS paper is in continuation of observations laid before the Society in 1829, regarding the anatomical characters of certain adventitious structures. The author had formerly shown that these structures assumed the type of compound nervous cysts. He also shewed that there existed great differences dependent on the material by which this form may be assumed, and the organization it receives. The author next refers to the labours of Dr. Carswell and Mr. Kiernan, and then goes on to say that, in 1838, he visited Berlin, and received from Professor Schwann a demonstration of the nucleated cells, which he had pointed out as forming an essential part in animal and vegetable tissues.

The objects which arrest attention when a portion of one of the structures alluded to is placed in the field of the microscope (if this be of sufficient power) are as follow.

1st. Nucleated cells of various shapes and sizes.

2ndly. A substance having a filamentous character.

3rdly. Granular matter without definite shape, the particles of which are often smaller than those of the nucleated cells, but by combination

forming masses of comparatively large size.

4thly, Very minute spherical particles resembling fat globules, and also much disposed to aggregation.

5thly, Crystals, having for the most part a rhomboidal character, and often forming mackles.

6thly, and lastly, A transparent fluid, in which these objects are contained, and which is made evident by the motion which it permits to take place between them.

Dr. Hodgkin then enters into a very elaborate discussion on the subject, into which, however, our limits prevent us from following him. He concludes by drawing the following conclusions—

1st. That continued observation has confirmed the constant presence of the type of compound serous cysts in a class of adventitious structures, which comprehends the whole family of cancerous diseases. I may add that I have found it, not only in man, but also in the inferior animals, as, for example, the horse, the ox, the cat, and different species of birds.

Several practised observers have fully confirmed my conclusions, and I may here be allowed to record that the late Professor Delpech, and the present Professor Rokitański, have personally informed me that they had independently been led to take similar views.

2ndly. That the microscopic examination of these tissues, though extremely interesting, does not furnish perfectly conclusive tests of any particular form of adventitious structure to which a specimen may belong; but that it demonstrates the application of the nucleated cell theory, whilst it is fatal to that of cancerous matter being formed in the blood, and eliminated at the spots at which the tumors become manifest. It therefore furnishes an important argument in favour of operation, though other practical considerations require to be attended to before operation is decided on.

3rdly. That to have a complete view of the mode of production of these structures, we must combine the cell theory of Schwann and Müller, the coagulation principle which I had previously suggested, and the process of organization investigated by Kiernan—three stages of development which appear to occur in the order in which

they have been enumerated, and that none of the phenomena, taken singly, is an adequate test of malignancy, which, as stated in my first paper, must be regarded as the sum of several characters.

4thly. That chemical analysis, though extremely important and interesting, affords an imperfect and inadequate criterion; as the principles concerned may vary, or be changed, in the progress of development.

5thly. That in operating for the removal of a tumor of this class, it is extremely important to leave behind none of those minute cysts which often form granules in the surrounding cellular membrane, though it may appear to be, in other respects, perfectly healthy: this appears to be a mode of extension of the disease, independent of inflammation.

6thly. That experience teaches us that the infiltrated form of these diseases occurs in the structures in the neighbourhood of the purely adventitious growth, when these structures have been the seat of inflammation, and that the chances of success from operation are consequently infinitely diminished when such surrounding inflammation has taken place. The presence of the peculiar matter of the disease, in the interior of vessels, appears to be one of the modes in which infiltration, the result of inflammation, exhibits itself, and is, therefore, not a valid argument in favour of the pre-existence of such matter in the circulating blood.

An Account of a Case in which a Foreign Body was lodged in the Right Bronchus. By Sir BENJAMIN C. BRODIE, Bart. F.R.S. Surgeon-General to the Queen, &c. &c.

This is a very interesting case, of which, however, we gave a full account in a former volume*. We shall merely state now that a gentleman placed half a sovereign in his mouth when playing with some children, and that it slipped behind the tongue: this was followed by vomiting, coughing, and straining, during which the piece of money was thrown into the trachea, and became lodged in the right bronchus. Fits of coughing, and other inconveniences, resulted; and, after various ineffectual

* Vol. 2, 1842-3, page 540.

expedients to get rid of the foreign body, an artificial opening was made in the trachea between the thyroid gland and the sternum, in order that, if the coin were within reach of the forceps, it might be extracted; and that, if not, the opening might serve as a kind of safety valve. It was found impossible to remove it, and various trials were made of the inverted posture without success. At length, on the 13th of May, the patient having been placed on the platform, and brought into the same position as formerly, the back was struck with the hand; two or three efforts to cough followed, and presently he felt the coin quit the bronchus, striking almost immediately afterwards against the incisor teeth of the upper jaw, and then dropping out of the mouth: a small quantity of blood, drawn into the trachea from the granulations of the external wound, being ejected at the same time. No spasm took place in the muscles of the glottis, nor was there any of that inconvenience and distress which had caused no small degree of alarm on the former occasion.

The only papers which remain are those of Mr. Toynbee on the Pathology of the Ear, Mr. Shaw on Rickets, and Dr. Webster on Insanity; full reports of which we gave at the time of their being read.

MEDICAL GAZETTE.

Friday, November 17, 1843.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

STATE OF MEDICINE ABROAD.

DURING the last eight or ten years a very remarkable and interesting change has been going on among our neighbours, and is still busily at work, as respects some of the fundamental points in the history of disease. The doctrines of solidism, so long almost universally received, and seemingly so well established, are beginning to give way on every hand to those of a modi-

fied humoral pathology. Broussais and all his favourite notions have for some time past been at a great discount; the more sagacious of his disciples seem quite ready to yield up first one position and then another; and, while explaining away some of the extravagancies of the system, to admit within the pale of their creed other morbid agencies besides those of irritation and inflammatory excitement. Even in the writings and lectures of M. Bouilland, unquestionably one of the ablest of this party, we may observe symptoms of an uneasy consciousness that some of his long-cherished views have been carried rather too far; and M. Forget, the clever professor of the Strasbourg school, has lately begun to recognise the possibility of an altered condition of the fluids having something to do with many febrile disorders.

Several circumstances have occurred of late years to promote the change to which we allude. For example, the grievous want of success on the part of the medical officers of the French army in the late expedition to Africa, in treating the diseases that caused such ravages among the troops, has had no little share in opening the eyes of the profession throughout France to the errors of the system on which they have been hitherto acting. During the first two or three years after their occupation of Algiers and the surrounding districts, the mortality was truly frightful: all the hospitals were constantly full, and the proportion of the deaths to the recoveries was distressingly great. What with the unhealthy nature of the climate, the extreme hardships of the military service, the unsatisfactory character of the warfare, and the consequent *abattement* and discouragement which the French soldiers above those of every other nation are subject to when success does not shine upon them—these were amply suffi-

cient causes to account for the large number that was constantly on the sick list. The prevailing diseases were fevers of different kinds, chiefly of a remittent and intermittent character, but not unfrequently assuming all the features of bad typhus. Now, how were the medical men of the army prepared for the encounter? and what means did they take to baffle or subdue the enemy with which *they* had to do? Most of them, as a matter of course, young or middle aged men, and who had been educated in Paris within the last ten or fifteen years, had scarcely heard of any other kind of fever save and except gastrite, or gastro-enterite, or dothin-enterite, or some other *ite* (unless, perhaps, *fièvre typhoïde* may have been introduced to their notice for a change), and were almost quite ignorant of what even their own countrymen, far less what the medical men of other nations, had observed in other tropical regions. Their minds being charged with home notions of disease, and with these alone, they could at first see nothing in the contumaciously obstinate, or rapidly fatal, fevers of their newly acquired province in Africa, but grave forms of what they had previously witnessed in Paris—a great and most pernicious mistake! We need scarcely add, that the treatment pursued was strictly in accordance with the most approved system of the metropolitan hospitals. The poor soldiers suffered terribly in consequence of all this; and the medical men themselves (many of whom unfortunately perished) frankly confessed that they became quite aghast at the utter impotence of all their efforts against the disease with which they had to contend.

This state of things continued, we believe, for two or three years; the fevers, as a matter of course, every now

and then experiencing fits, so to speak, of increase and remission, according to the state of the weather, the season, the fatigues of the service, and so forth. At length M. Boudin, one of the medical staff, shrewdly suspecting that most of the cases of the African fever were rather of a remittent or intermittent than of a continued type, began to administer quinine and other tonic medicines in place of the lemonade and leeches that had been so much in vogue. The almost immediate diminution in the weekly bills of mortality bore abundant witness to the value of the change that had been made. The rest of the medical corps were not tardy in following the good example that had been set them, and the difference of opinion soon became not as to the mode of treatment to be pursued, so much as to the mere amount of quinine that required to be exhibited, or the comparative efficacy of bark and arsenic.

Something very similar to all this has occurred within the last year or two in France. An epidemic disease, rather novel in some of its features, made its appearance in Strasbourg, Avignon, and other towns. The chief symptoms were pyrexia (often very imperfectly marked), intense headache, severe pain along the spine, tendency to spasm and rigidity of the muscles, vomiting, &c.: delirium and coma almost invariably preceding death, which in many cases occurred in either 48 or 60 hours after the invasion. Now, this disease was at first regarded as a genuine inflammation of the brain and spinal marrow, and several learned memoirs were written on the so-called “epidemic meningitis or cerebro-spinitis.” It was most heroically attacked with blood-letting, and all other sorts of depletion. Well, what was the result? More than one half of those that were seized,

died. This certainly was not at all satisfactory; but fortunately, at this time, an incidental discovery (as it was called) led to an important change in the remedies used, and to a marked diminution in the amount of the mortality. A physician in Avignon, having administered a dose of opium to one of his patients for the relief of some casual symptom, was surprised to find next day that the cerebral disturbance, so far from being aggravated as he had feared, was most effectually relieved, and that his patient was altogether decidedly better. He was therefore induced to repeat the dose, and the result seemed to be that the recovery was in a great measure attributable to the use of the medicine. Subsequent experience fully confirmed the truth of this idea, and M. Chauffard had the satisfaction of witnessing the practice which he had introduced, almost universally followed, and with very pleasing consequences. We should mention that saline aperients, cinchona, &c. were usually combined with opium. So much for the alleged epidemic of inflammation of the brain and spinal marrow.

With such histories as these before their eyes, it is not surprising that our mobile neighbours are beginning to modify their opinions on the subject of fever. But there are other causes at work, all tending to the same end—that, we mean, of introducing into favour the doctrine of a humoral pathology. One of the most important of these is unquestionably the great attention that is now paid to organic chemistry, in consequence of the remarkable impulse that has been given to this science by the recent researches of Liebig on the subjects of respiration, nutrition, and other functions of animal bodies. This truly original thinker has thrown out some valuable hints that

serve to throw some light on the difficult question how fevers may arise from the introduction of a morbid poison into the blood. Whether his ideas be correct or not, they cannot fail to recal to the mind of the well-read physician, the doctrines of the older authors about ferments, acrid humours, and so forth.

This leads us to notice another agency that is beginning to exercise some influence upon the profession, not in France only, but in this and in other countries also—we mean the taste that seems to be springing up for the perusal and study of the ancient classics of medical literature. Last season there was actually a *seance* of one of the medical societies occupied with discussing the comparative merits of the Hippocratic and Galenian doctrines, and we now not unfrequently find in the lectures of some of the metropolitan physicians allusion to the opinions of such men as Sydenham, Stoll, and Baglivi.

In conclusion, we may point to the recent researches of Andral on the changes which the blood undergoes in various classes of diseases (*vide* his *Essai sur l'Hématologie*), as likely to have a very salutary influence in directing the minds of his professional brethren to more enlarged and correct views in this department of pathology. There are, no doubt, other causes we might mention; but we leave the consideration of these to another opportunity.

EXAMINATION
IN
MATERIA MEDICA AND
THERAPEUTICS,

*For Prizes given by the Society of
Apothecaries, October, 1843.*

1. State the mode of preparation, chemical changes and composition, the physical properties, physiological action, and practical uses of the *Potassii Bromidum*.

2. State the mode of preparation and the physiological effects of *Antimonii Potassio-tartras*.

3. In what diseases is the *Antimonii Potassio-tartras* exhibited; in what doses; and in what modes of combination is it most advantageously prescribed?

4. Describe the preparation of *Barii Chloridum*, its physiological effects, and its practical uses.

5. Enumerate the preparations of iodine, state their physiological action, and the diseases for which they may be prescribed, with their doses, and modes of combination.

6. Describe the preparation, the modes of operation, and the medical uses of *Potasse Chloras*.

7. Describe the preparation, the physiological effects, and the uses of *Bismuthi Trisnitras*.

8. State the modes of preparation, physical properties, physiological action, doses, and practical uses of *Zinci Sulphas* and *Zinci Chloridum*.

9. Enumerate the class of diuretic medicines, and arrange them according to the modes in which they may be supposed to operate.

10. What means of recovery would you employ in cases of poisoning by opium, or by other narcotic substances?

The prizemen were—Mr. Frederick John Hensley, gold medal, of King's College; Mr. Henry Southerin, silver medal, of University College.

ON VIVISECTION.

BY ROBERT HULL, M.D.

Letter III.

THE world lies under great obligation to the biographer of Sir Astley Cooper. With a rare magnanimity, the author has combined a tender tribute of affection with a manly display of truth.

The famous surgeon has been painted with his darker as well as brilliant surfaces. The chiaroscuro is complete.

Among the shadier traits of this master-surgeon are his vivisections. See the wretched dogs, who administered to his rural sports, dreading to approach their zootomical lord. "*Cor caninum habentem fugient canes*," saith Pliny.

"It rarely happened but that one or two of the dogs which we had out had been submitted to operation. Some amusement was always afforded by the timidity which these animals manifested when near my uncle." Amusement!

Behold how a departure from humanity may lead a man farther—to processes of a

furtive kind, which it is wonderful how a gentleman could reconcile with his fine sense of propriety.

"Charles has known thirty dogs, besides other animals, in the hay-loft, subjects of experiments. To obtain these, Charles used to employ the servants, and to allow half-a-crown for each dog. This temptation, I have reason to believe, led to a frequent breach of the laws relating to dog-stealing.

"My uncle's coachman, passing down Wormwood Street, a dog seemed inclined to follow. Michael thought it advisable to secure him by a handkerchief.

"The dogs were not unfrequently procured in this manner. Nothing but the objects which led to these delinquencies could offer an excuse." No, indeed! But can any possible objects justify a gentleman, that he should condescend to connive at theft?

Of those piteous, kidnapped dogs, how farcical to delay their torments until some days had elapsed, "and no owner would come to claim." Who *could* claim them? Who could know that the faithful companion he has missed and deplores is secreted within the cold murky walls of a ruthless anatomist, soon to be mangled, mutilated, knifed; with no friend to protect him, no spectator to pity him, no manly and indignant master to rescue him from the furtive physiologist?

"One day a dog followed us, and accompanied us home, little foreseeing the fate that awaited him. First, the tying one of the femoral arteries: when the dog was recovered, one of the humoral arteries. After a few weeks the animal was killed, injected." How was the confidence in human protection displayed by this dog, abused, betrayed!

"Dr. Haighton and Sir Astley were disputing. Sir Astley made a remark to controvert certain experiments made by the Doctor. The 'merciless Doctor' made no reply, but ordered a pet and favourite spaniel to be brought, and put a period to his existence. He then demonstrated the results of a rigid operation to which the animal had been subjected three years preceding." This is the anecdote the Quarterly calls "hellish." Such are the preceptors whom the youth of England are sent to London to revere and imitate. Of this dog the tendo-achillis had been cut asunder, his femoral arteries subjected to operation, his nerve of voice divided, as the narrator rather thought to prevent his making known his subsequent sufferings!

Surely, after this publication, ladies and gentlemen will be cautious whom they employ as their medical advisers, lest the presence of the family surgeon involve the absence of the family dog.

The dog is the most interesting of all

animals: endowed with all the moral qualities of man, with much of his intellect. Such is the testimony of all ages, from Homer to Pliny, from Bingley to Blaine. Any cruel treatment of this creature which would not be tolerated towards men is decidedly immoral; and, if life be sacrificed, murderous.

I appeal to natural feelings, to implanted sensibility, to heaven-born tenderness. If, on reflection, philosophers can mutilate, torment, slay, this wonderful animal, I am not Christian enough to pray for mercy on themselves. I entertain a hope that, in a future world, the cruel investigators may meet a talionic recompense: that the victims will become the operators in turn. Nor let the cyrotomist deride the possibility.

ὅρα τὸ μέλλον πόλλ' ἀναστρέφει Θεός.

The canicide might peruse in Pliny the marvellous character of this quadruped—enough to preserve his knife from cynic blood, his fame from cloudiness. He would learn that of all animals the dog and the horse were the most faithful friends to man.

When Jason, of Lycia, was slain, his dog refused all nourishment, and died of hunger.

When Sabinus and his slaves were put to death, a dog belonging to one of these would not be driven from the jail, nor separated from the body of his master. The place resounded with his howlings; and when a bystander offered him food he carried it to the mouth of the dead man. When, at length, the corpse was thrown into the Tiber, he swam in and tried to raise it.

Is this an animal to be tortured?

I hope the Sydenham Society will not forget to publish those parts of Pliny which tell upon the physiology of brutes, the pathology of men.

But I trust that a brighter era is arising on the destinies of these animals; and the formation of anti-cruelty societies cannot fail to usher it. The example has been set in London; and the provinces approve and are following.

In Norwich, an association protective of animals has been founded; and among the active members three are hospital surgeons. The names of Crosse, Johnson, Dalrymple, are an assurance to the public that all surgeons are not barbarian zootomists; to medical students, that success, fame, opulence, may be secured without performances which entitle to a lodgment in the nearest jail.

In Bury St. Edmunds a similar society has been instituted; and one of the most active founders is Mr. Smith, the senior surgeon of the County Hospital.

The vivisectors cannot, of course, enter into the depths of that well-grounded suspicion, that there may be a future existence

for the brute creation. Yet this is a sentiment which has been advocated by some of the holiest divines, some of the wisest moralists.

It harmonizes with all arguments for the immateriality of mind, for the natural immortality of the soul. It solves the most difficult problem in the moral government of the Great Spirit. It reconciles us, without farther hesitation, to the unanswerable assertion of the Bible, that "God is love." To the vivisector who tortures whom God has created for use, who destroys whom the Deity intended for life, I would say, with the great and good Euripides, and with all imaginable contempt—

σκαὸς πέφυκας, τοῦ Θεοῦ πλείω φρονῶν.

Norwich, Oct. 28, 1843.

CAUTIONS TO MEDICAL STUDENTS.

To the Editor of the Medical Gazette.

SIR,

THE welfare of medical students should be a matter of great interest to lecturers; to the medical journalist it is evidently so, from the pains which he takes in circulating all the branches of learning connected with our profession. The medical periodicals are in fact journals of education.

It is always unpleasant to contemplate the dark side of a picture, but we are occasionally compelled to do so in our intercourse with human nature, and as there is frequent communication between lecturers and students, it affords the former opportunities of seeing a great variety of character among them. The following portraits, although darkly shaded with the less favourable qualities of medical students, form, I believe, exceptions to the general rule, for the majority of them are anxious to qualify themselves in a proper manner. The cases are not assumed merely for the occasion, but actually occurred, and you are at liberty to publish them, if you think they are calculated to act as beacons to deter others from adopting a similar course.

It sometimes happens that a student has gone through all the branches of education with the exception of attendance on one course of lectures: a lucrative partnership offers itself; his schedule contains the signatures of the different lecturers to their respective subjects, excepting the one already alluded to. What expedient does he have recourse to? He hastens to the lecturer on that particular branch, and implores him to attach his signature to the blank part, certifying that the course has been attended.

otherwise his prospects in life are ruined. He admits negligence, but says that he has only one course, and pleads *the facility with which a signature can be attached*, and that he will tell nobody. The lecturer refuses to acquiesce: he then offers the double fee! This plan fails, and he departs in despair.

Another student applies dressed in mourning and depressed in his appearance, requiring a certificate of attendance on a particular course of lectures, which he has neglected to attend under the impression that no inconvenience would ensue from their postponement. He states that he did not imagine it would be necessary for him to enter into practice so early, but in consequence of the sudden death of his father, and his aged mother being unable to support him, he wishes to become a member of our profession. Tears follow the non-compliance with his request, and he is compelled to wait perhaps another year before his qualifications are complete.

A third anxiously desires the signature of a lecturer on the ground that his father has written for the schedule in order that he may see the names of the lecturers attached to the different certificates. He has become greatly alarmed, for some of the courses have not been attended, in addition to which he acknowledges having received from his father money sufficient to pay for them, but instead of entering to the lectures he has betrayed the trust reposed in him, and confesses he has been "too gay." His anxiety increases lest he should be detected in an untruth, having already informed the parent that he entered to all the subjects required in medical education.

Perhaps the publication of these remarks in your periodical may meet the eyes of a few students similarly disposed early in the present session, and act as a caution for them to be on the alert to qualify themselves in every respect, in order that they may be able to undertake duties likely to benefit others, as well as to advance their own prospects; and 2dly, in the event of being suddenly deprived of parental resources, they may be prepared to overcome the exigencies of life by their own independent exertions; and thirdly, it may be the cause of preventing them from misapplying the money entrusted to them by their parents, and throwing it into the lap of dissipation, which will cripple the means for obtaining knowledge likely to be the source of much happiness in their youth and comfort in old age.—I am, sir,

Your most obedient servant,

C. J. B. ALDIS, M.D.

Old Burlington Street.
Nov. 4, 1843.

STATISTICS OF INSANITY IN FRANCE:

INFLUENCE OF CIVILIZATION.

THE following letter was read by M. Briere de Boismont at a recent sitting of the Royal Academy.

"Five years ago, I had the honour of reading a paper before this learned assembly upon the influence of civilization on the production of insanity, and I then endeavoured to shew, by reference to numerous tables, that the frequency of this most melancholy affliction increases proportionately with the advances which a nation makes in social and mental attainments. Whatever opinion may be formed on this subject, no one can dispute the fact that moral causes give rise to alienation of mind more frequently than those of a purely physical or bodily nature. In 1897, Pinel distinctly enounced the truth of this position. Out of 683 cases, which had occurred within his own observation, as many as 464 were clearly attributable to moral causes. Esquirol, too, has added his valuable testimony to the same effect; for out of 274 cases which he has reported, 167 were traceable to the influence of psychical disturbance. According to the recent very elaborate researches of M. Parchappe, the relative number of cases arising from mental and from bodily causes is in the ratio of 63 to 37—the first being, therefore, nearly double the second.

If, then, the influence of the one cause be so much greater, and so much more generally felt than that of the other, we cannot be surprised to find that the frequency of insanity should increase with the advances of civilization, more especially in those countries where the mind is more worked and excited than elsewhere.

It is exceedingly difficult to obtain exact reports of the number of the insane in different districts of France. Although government has expressly ordered that each department should have its separate institution, this is still but very imperfectly carried out in various parts of the country.

M. Guislain, whose excellent works on mental disorders are universally appreciated, has stated, in his official report published by order of the Belgian Government, that the number of the insane in that country (as far as can be ascertained) is 5105, out of a population of 4,165,953 inhabitants; but he adds that this number gives only about two-thirds, or so, of the entire amount, in consequence of the number of insane persons dwelling in boarding-houses, convents, &c.

M. Boismont calculates the number of the insane in France at nearly 30,000.—*Medico-Chirurgical Review.*

ATROPHY OF THE HEART IN PHTHISIS.

DR. STOKES said the specimens which he wished to present to the Society at that meeting were possessed of considerable interest. They were from the body of a man who had died of phthisis at a very advanced age. The heart presented an appearance which he believed had been remarked previously by only King, of London, and R. Adams and R. W. Smith, of Dublin. In the present case there was atrophy to an extreme degree of the heart, a condition already remarked as occurring in chronic phthisis, the heart observing the law of the atrophy of voluntary muscles, but what he particularly desired to direct the attention of the Society to, was the atrophied state of the aortic valves in this specimen; they were very thin, and in some places cribriform. The filaments corresponding to the perforations were as delicate as a spider's thread. The tongue of this patient was very red, smooth, and dry, but there was no inflammation of the stomach. This appearance of the tongue, usually designated *the beefsteak tongue*, has been also observed in fevers where there was no coexistent gastric affection; it is therefore not to be viewed always as a proof of gastric disease. The cavern in the lung was very large, and contained but little fluid; as it became dry the metallic sounds became audible; in the early stage of the disease, while there was fluid, there was gurgling, and the sounds could be modified by change of position. When the cavern had become dry, the expectoration ceased, but a little before death it was restored, and this was explained by finding in the opposite lung two small recently formed cavities. One hydatid was found in the kidney. As during a part of the progress of this case, the cavity in the lungs gave the metallic sounds as observed in pneumothorax, the diagnosis from pneumothorax was based on the signs which indicated the costal and pulmonary pleura to be in apposition.—*Dublin Journal of Medical Science.*

EXPERIMENTS AT THE GROTTA DEL CAVE.

M. CONSTANTIN JAMES having lately visited Naples in company with M. Magendie, took the opportunity of making some observations and experiments at the Grotto del Cave. This well-known natural curiosity, situated at Puzzuoli, on the slope of a very fertile hill opposite the lake Agnano, is a cave, the walls and roof of which have the appearance of being rudely cut out of the solid rock, but it is not certain whether the excavation be natural or artificial. From

various points of the surface there arise small bubbles, which bursting, deposit at the floor of the cave a carbonic acid, slightly whitened with watery vapour. Lime water dropped from a bottle becomes turbid on reaching the floor of the cave; a pistol with a flint lock repeatedly missed fire, but at last the smoke from its discharge settled on the surface of the gas, and enabled the depth of the stratum to be accurately measured. It was found to slope downwards, from the back of the grotto to the entrance being 60 centimetres in depth at the back, 35 in the middle, and 20 at the entrance. The stream of carbonic acid thus constantly flows over the threshold, and may be traced some way down the hill; at the distance of two metres it extinguished a candle. Even the air at the top of the grotto slightly whitened lime water.

M. James details several experiments which he made first on himself and then on animals. The dog, which for three years has been daily subjected to the process of suffocation several times a day, is in good health, but dreads the process exceedingly. The effects of the gases are perhaps modified by habit and intelligence.

M. James first knelt down in the grotto, plunging his head into the gas for fifteen seconds without breathing; a little smarting of the eyes was the only effect perceived. The act of swallowing was then tried, and the agreeable sharp taste of the acid, reminding him of Seltzer water, could be perceived by merely fanning up the gas with the hand, without plunging the head into it. M. James then inhaled the gas, taking one strong inspiration, and was seized with confusion, giddiness, and constriction at the chest, relieved in a few minutes by breathing pure air. A more careful inspiration produced the same symptoms, with rather less feeling of suffocation, but a sensation in the forehead like that when carbonic acid escapes by the nostrils, from champagne.

A rabbit placed in the grotto near the door, where the stratum of gas was thin, escaped from its uneasy sensations by standing on its hind legs, but being placed further in it fell down in ten seconds; in seventy-five seconds all signs of life disappeared, but it began to breathe again after being five minutes in the fresh air, and in a quarter of an hour seemed well. Valuable experiments might be made here on the comparative efficacy of resuscitation. M. James tried a few, taking care in each case to immerse the animal in the gas for exactly the same length of time, seventy-five seconds. Cold affusions, and cold-water lavements, contrary to expectation, did not hasten recovery, though the animals seemed to recover their strength more completely after their use. Of two rabbits after immersion, one was made to

respire acetic acid (vapour), the other ammonia. The former recovered long before the latter. Alternate pressure of the chest and belly assisted recovery, but by far the most efficacious treatment was breathing carefully into the lungs of the animal. Those treated in this way began to recover in twenty seconds; those left to themselves showed no signs of life under five minutes. Forcible insufflation seemed rather less efficacious; gentle breathing seemed more in accordance with the gradual efforts of nature to restore the interrupted function. No rabbit was found to recover spontaneously after two minutes' immersion, but two were immersed for three minutes. One was restored in a quarter of an hour by breathing into its lungs, the other left to itself died. On opening the body, the right side of the heart was found gorged with blood, which hardly reddened on exposure to the air; the liver and spleen was also gorged; there was no effusion into the pleura or peritoneum; the fluidity of the blood was remarkable. Remembering the experiments of M. Magendie on the loss of coagulating power, M. James delayed the examination of another rabbit till eight hours after death.

The fluid blood had then transuded in various parts; the peritoneum and pleura contained bloody fluid, and blood could be pressed out of the ecchymosed surface of the lungs. The different appearances in two animals dying under exactly similar circumstances shows how much obscurity attends our examination of the human body, which seldom takes place within twenty-four hours after death. According to the account of the keeper, the following is the time required to destroy life in various animals which he had seen killed by immersion in the gas of the grotto; an account verified by M. James only in the case of rabbits and frogs.—

	Minutes.
Adder	7
Frog	5
Cat	4
Dog	3
Rabbit	2
Fowl	2

How long does man live in this gas? It is said that three centuries ago the Prince of Toledo tried the experiment on a criminal, tied hand and foot and laid at the bottom of the cave, and that the unfortunate prisoner, taken out in ten minutes, was found dead.

No comparison can be drawn between death so produced and that from the fumes of charcoal. In the latter case, the gas becomes gradually mixed with the atmospheric air; while in the grotto there is a stratum of pure carbonic acid, which produces almost instantaneous suffocation, like that sometimes caused by an imprudent descent into fomenting vats, or deep excavations.

No vegetables are found growing in the grotto; those which are placed there soon perish. The soil of Puzzuoli is essentially volcanic, and abounds in thermal waters, most of which contain much carbonic acid. The earth at the floor of the grotto a little below the surface is two degrees warmer than the air, which is 38° Cent. Bubbles rise to the surface in two or three places on the near side of the lake Agnano, which is a few paces off, and five or six metres below the level of the grotto.

When the lake is clear, currents are seen passing from the direction of the mountain; the temperature of the water is not raised, and the bubbles, when collected in inverted test tubes, were found to extinguish a candle, and to whiten lime water. Doubtless a current of thermal water passes under the grotto into the lake, and furnishes an unfailing supply of the gas through the light and porous soil.—*Gazette Medicale*.

STRICTURE OF THE TRACHEA.

MR. O'FERRALL said the specimens he had to lay before the Society belonged to a very interesting case of disease of the trachea, which had come under his notice in St. Vincent's Hospital. The subject was a female, aged 26 or 27 years, who had been a patient in that establishment several months ago, while she was suffering from phagedænic ulceration of the throat. She was successfully treated, and was discharged; but, in five or six months afterwards, returned to the hospital affected with stridulous breathing, a teasing cough, loss of voice, and extreme difficulty of deglutition. When the finger was introduced into the fauces, the epiglottis felt ragged and shortened: the respiration was feeble all over the chest, but no part sounded dull, and there was no evidence of either solidification of the lung, or of the existence of any tumor within the thorax. This woman died suddenly. Fumigations had been used, and had given a little ease. Tracheotomy was proposed, but decided against; and the examination after death proved that this decision was correct. The epiglottis was found to have been partly destroyed; the right arytenoid cartilage also was in a state of ulceration, but both appeared to be healing: the trachea itself was contracted; its parietes pressed together; the lining membrane was a pale yellow colour; the cartilages were softened, and the distance between them lessened; posteriorly the situation of the membranous portion was occupied by a growth of dense firm matter, which was connected with the cellular membrane behind, which was in a thickened state: below the cricoid cartilage the calibre of the trachea was strictured so that only a

very small bougie could be passed through; at the strictured point there had been ulceration of the mucous membrane. The diagnosis in this case was peculiarly difficult; the stridor in breathing was insufficient to point out the exact nature of the disease; its situation could not be discovered by auscultation, for it was equally intense in every part of the course of the trachea. It is known that stridulous breathing may be produced by pressure on the trachea, below the larynx. This case presented a new cause of stridor. It was evident, by examination of the specimen, that tracheotomy would have been quite ineffectual, as the opening would have been made just above the strictured part of the canal.—*Dublin Journal of Medical Science.*

ARSENIC IN INVETERATE SYPHILIS.

A WOMAN, who had lost the whole of her palate from syphilitic ulceration, and was in a most deplorable state of suffering, so that there seemed scarcely any chance of ultimate recovery, was put upon a course of the arsenical solution (*Fowler's*): she began with three drops, and gradually raised the daily dose up to thirty.

After continuing the use of the medicine until she had taken two ounces of the solution, the amendment was truly surprising; the ulceration was arrested, and the general health rapidly improved: the power of deglutition also was almost completely restored.

In the same German journal (*Hæser's Repertorium*) is reported a well-marked case of scirrhus of the mamma, where the progress of the disease seemed to be quite arrested by the internal use of the Iodoret of Arsenic: in the course of six months, as much as 135 grains of this very active remedy were taken. It should be mentioned, however, that an issue was at the same time inserted in the corresponding arm—a remedy, by the by, that should seldom be omitted in the treatment of all malignant formations.

(Of late, the Chlorate or Oxymuriate of Potass has been tried, by many of the hospital surgeons in this metropolis, in cases of lupus, unhealthy ulcerations, &c. with very decided benefit—the dose from five to ten or twenty grains three times a day.)—*Med. Chir. Rev.*, from *Bibliothek für Lager.*

A CASE FOR THE HOMŒOPATHISTS.

Amaurosis following retrocession of itch.
By DR. FELSACH, of Ischl.

A GIRL, rather more than 20 years of age, strong and healthy, with dark well-formed eyes, was suddenly seized with *muscæ volitantes*, the appearance of sparks, and di-

minished power of vision in both eyes. Except some sluggishness of the pupil, nothing unusual appeared in the eyes; the spinal marrow was also unaffected. It was found that, three years ago, she had itch, which disappeared under the use of sulphur-ointment. M. Felsach attending to this circumstance, ordered the internal use of three grains of flowers of sulphur night and morning for six weeks.—*Gazette Médicale*, copied from the *Oesterreichische Medicinische Wochenschrift*. What would a dose or two of purgative medicine have done in this case?—[Tr.]

CLINICAL REPORTS OF CASES

TREATED AT THE GLASGOW EYE
INFIRMARY.

By WILLIAM MACKENZIE, M.D.

Some account of the epidemic remittent fever prevalent in Glasgow in 1843—Its resemblance to some of the Dublin epidemics—Its identity with the Dublin epidemic of 1826—Cases of affection of the eyes resulting from the Glasgow fever of 1843—Remarks on the statistics, symptoms, diagnosis, stages, predisposing and exciting causes, prognosis, and treatment of postfebrile ophthalmitis.

THE cases of eye-disease, which I am now about to comment upon, being the result of an epidemic fever which has prevailed in Glasgow during the greater part of 1843, it may be proper to give some account of the fever itself, before proceeding to describe the very serious affection of the eye, to which in so many instances it has given origin.

A remarkable change has taken place in the epidemic constitution of Glasgow during the present year. Exanthematic typhus, that is to say, a continued fever, characterized, along with other symptoms, by an eruption over the body resembling measles, averaging a course of twenty-one days, and proving fatal to an extent of about 10 per cent, has been supplanted by a remittent fever, sometimes attended with petechiæ, but not with the measly eruption, often accompanied with jaundice, its first paroxysm coming to a crisis within seven days, a relapse happening almost invariably, but the patient rarely suffering more than two paroxysms, and the mortality not exceeding $3\frac{1}{2}$ per cent.

This remittent fever has prevailed chiefly from the beginning of June to the end of September; but I am informed that the

disease existed as early as September 1842*, although it was then generally regarded as a catarrhal fever or influenza, or as a simple continued fever. Since the first week of October 1843, the number of cases has sensibly decreased. The disease has prevailed only among the poor, and in the ill-ventilated and filthy parts of the town. Any cases which have occurred among the better ranks have generally been traced to the communication of the individuals seized, with patients in those parts of the town where it abounded. Among the poor, no febrile disease, that I am aware of, has spread to the same extent. Since January, probably 15,000 persons have been affected with it in Glasgow.

Symptoms of the fever.—The disease commences with the usual symptoms of fever—rigors, headache, and sickness. A striking feature is the frequent and excessive vomiting, or straining to vomit, attended by pain throughout the whole body, somewhat resembling rheumatism. There are often no premonitory symptoms, the attack being very sudden, and marked by excessive weakness. One little boy, whom I saw, was seized on the street, and fell down, so that he required to be carried home. In some of the cases, the disease resembles very much sea-sickness in its accession, both in respect to the prostration of strength by which the vomiting is accompanied, and the total indifference of the patients whether they live or die.

The pulse, in general, is not greatly accelerated, averaging about 100. The tongue is not much loaded, but rather clean; after a time it becomes brown and dry. Especially in the night, the patient is delirious; he is often affected with subsultus tendinum; he cannot sleep, tosses continually, and insists on getting up.

* For a number of facts regarding the fever, I am indebted to Dr. Hugh Kennedy, one of the District Surgeons.

Epistaxis in some, and jaundice in others, are of frequent occurrence. When the disease attacks women about the menstrual period, the discharge is very copious; and almost all the women in a state of pregnancy, who are seized, abort, if in the early months, or have premature labour, if farther advanced. If pregnant women, affected with the fever, go the full time, sometimes the child is dead; or, if born alive, the mother has no milk, and has a troublesome and lingering recovery, while the child generally dies for want of support, or perhaps from being affected with the fever.

At the height of the disease, the symptoms are the same as at the beginning, only of greater violence. A convulsion-fit is not an uncommon thing immediately before the crisis.

There is no certain period when the first crisis happens. The patient is generally several days ill, say five or six, when a decided change takes place by profuse perspiration during the night, generally preceded by a severe rigor. Next morning the patient expresses himself as if in a new world; the tongue has become moist, the thirst is greatly abated, and he is free from sickness and headache. In old people, there is little or no perspiration at the crisis; but the change is at once observed by the more agreeable expression of the countenance, and the manner of speaking.

Some patients have a very short remission, and others have one of considerable length. In some it lasts only for three or four days; in others for two or three weeks. Very few escape a return of the fever. Whether they get up, and perhaps go out of doors, or confine themselves closely to bed, nineteen out of twenty relapse. Where the first attack is mild, the second is generally more severe, and *vice versa*. If any improper freedom be used in diet during the remission, the second attack is generally more severe than the first.

The relapse occurs with the very same symptoms as the original attack. The patient, whom the day before we had left to all appearance convalescent, we now find again in the height of the fever; he is excessively weak, and his countenance is often shrunk to such an extent, as to remind one of the collapsed state in malignant cholera. His skin is covered with a clammy disagreeable perspiration.

The general duration of the second attack is much about that of the first, the second crisis taking place sometimes in two or three days, but more commonly not before four or five. If there be any difference in the symptoms of the first and second attacks, it is in the pains throughout the body being of greater severity in the second. There is

also considerable pain in micturition. Dysentery sometimes attends the second attack, traceable not unfrequently to the use of spirits during the remission.

A second or third relapse is rare; but I am informed that some patients who had the disease about four months ago, with its paroxysmal character well marked, and who therefore thought themselves secure, have again been seized with it, and gone through all its stages a second time—a circumstance which, along with others already mentioned, serves to distinguish this fever from exanthematic typhus.

Various sequelæ are observed to arise from the present fever; such as pains in the joints, want of power in the extremities, œdema of the feet, enlargement of the glands about the neck, boils in different parts of the body, and long-continued debility. But the most remarkable is the amaurotic and inflammatory affection of the eye, afterwards to be described.

Treatment of the fever.—A question naturally occurs, whether this disease can be checked at the commencement by any particular mode of treatment; such as by emetics. So far as I have learned, attempts of this kind have been unsuccessful.

The treatment which has generally been adopted has been simple and symptomatic, consisting in perfect rest in bed, cold fomentations to the head, shaving the scalp, the application of leeches to the temples, and sometimes small blisters; turpentine cloths and mustard poultices have been applied to the epigastrium, some recommending abstinence as much as possible from drink, as drinking seemed to them to provoke the vomiting; others giving effervescing liquids, as soda water and ginger beer; keeping the bowels gently open by castor oil, avoiding drastic purges; in cases of jaundice, small doses of Blue pill frequently repeated, and blisters over the liver; checking dysentery by castor oil and laudanum; where there was much debility, putting the patient on wine and quina; and after the head symptoms were relieved, giving Dover's powder for the pains throughout the body.

On the question, whether quina prevents the relapse, I find there is a diversity of opinion; some practitioners finding it effectual for that purpose, but the generality either not trying it at all, employing it only in small doses, or finding it inefficacious. Wine, even in large quantities, does not prevent the relapse.

This fever appears to be highly contagious. Where many individuals, ill-fed and ill-clothed, live together in small, dirty, and ill-ventilated apartments, it has generally gone through the whole of them, young and old, in rapid succession. If the system of

those exposed to it is farther depressed by a fit of drinking, they are almost certain to be affected with the fever soon after.

It appears to have supplanted in a great measure all other diseases, especially typhus fever and dysentery.

The smallness of the mortality, compared with the severity of the symptoms, and the debility it leaves behind it, is a matter of surprise. Considering all the circumstances, it is wonderful that there have not been six deaths for every one that has occurred. The deaths have been chiefly among the aged, young children, and persons of broken-down constitutions.

This disease is never observed to merge into exanthematic typhus.

I have not witnessed the inspection of the body of any one who has died of this fever. I am informed that appearances of congestion have been met with in the head, great redness of the mucous coat of the bowels, especially in the vicinity of the cæcum, the spleen resembling apoplectic lung, the gall-bladder gorged with bile, &c. The optic nerves and retinae should be carefully examined.

I am unable to say whether this species of fever has ever been previously known in Glasgow. That it has at different times prevailed in Ireland is rendered highly probable from the fact that the course observed by some of the Irish epidemics corresponds exactly with that of the fever now present in Glasgow, while the complete identity of this fever with that which prevailed in Dublin in 1826, is proven by the exact similarity of the affection of the eye, observed as a sequela in both instances.

In Rutt's History of the Diseases of Dublin during forty years, we meet with several instances of an epidemic of the same character with that now under consideration. Thus in July, August, September, and October, 1739, a fever prevailed, which was "attended with an intense pain in the head. It terminated," says he, "sometimes in four, for the most part in five or six days, sometimes in nine, and commonly in a critical sweat: it was far from being mortal. I was assured of seventy of the poorer sort at the same time in this fever, abandoned to the use of whey and God's good providence, who all recovered. The crisis, however, was very imperfect, for they were subject to relapses, even sometimes to the third time." (p. 75.) He describes the same remittent fever as occurring also in 1740, 1745, 1761, and 1765; noticing as a circumstance of the disease in 1765, that the bowels were in some instances remarkably affected.

There appears considerable resemblance between the present fever and that described by Dr. Stoker, as prevailing along with

typhus gravior in Dublin in 1816. He speaks of it as a *typhus mitior*, its usual course being from three to nine days, generally terminating on or before the seventh day, but very apt to relapse on the third or fifth day from the favourable change.

The Dublin epidemic of 1826, with which the present fever corresponds so exactly in its effects on the organs of vision, was also a remittent fever, as appears from the accounts published* of it by Dr. Reid and Dr. O'Brien. It was often attended by jaundice, and by pains in the bones; its crisis happened generally about the seventh day; the patients were very apt to relapse; the number attacked was very great, but the mortality comparatively small;—in all which particulars its analogy to the present Glasgow fever is borne out. The following extracts from Dr. O'Brien's Report might be applied to the disease now prevailing in this city, with scarcely any modification:—

"The other species of fever, or that of the new constitution, which constituted the bulk of this epidemic, was one of short periods, terminating in three, five, seven, or nine days, but the second of those periods was the most frequent." * * * "In this fever the chain of morbid actions was rapidly formed and rapidly terminated, and the disease developed itself with energy from the commencement. The access was sudden, and usually came on at mid-day. The person previously in perfect health would then be seized with sickness at stomach, headache, pain in the small of the back, and chilliness. On the approach of evening all these symptoms increased, and the febrile paroxysm was fully formed; the chilliness increased to a rigor, and the nausea to vomiting, which harassed the patient for the first three or four days of his fever in the form of an empty straining, and frequently continued through its whole course. On the evening of the fifth or seventh days the *exacerbatio critica* commenced, which, mostly with the intervention of a rigor, but very frequently without this symptom, terminated in a profuse perspiration, which continued through the night, so that on the following morning the crisis was complete, and we generally found the patient convalescent. We frequently received the glad tidings from himself in the following words: 'Sir, I got the cool last night.' The cool, however, was sufficiently visible in his countenance before he opened his lips; but unfortunately in many instances it proved only a delusive truce to his sufferings. The patient was destined, perhaps, to be harassed by one, two, or three relapses, which pro-

* Transactions of the Association of Fellows and Licentiates of the King and Queen's College of Physicians in Ireland, vol. v. pp. 266, 512. Dublin, 1828.

longed the whole duration of his illness even beyond that of the most protracted typhus. In fact, the liability to frequent relapses was one of the most striking characteristics by which this fever was distinguished from all previous epidemics, at least which happened in our time."

"Relapses, generally speaking, were milder and shorter than the original fever; but to this many exceptions occurred. The general symptoms of the summer variety of this fever, in addition to those already mentioned, were—acute headache; delirium, always active, sometimes phrenitic; rapid and hard pulse; white tongue with florid edges, but sometimes natural; muscular and arthritic rather than deep-seated pains, or, as they are termed, 'pains of the bones,' not accompanied, however, by swelling of the joints, except in a few instances; the skin in many cases of a light yellow tinge, and sometimes, though rarely, assuming the intense icteroid yellow, characteristic of jaundice and true yellow fever."

"The pathological exposition of this appearance the author believes to be simply this, that irregular jaundice supervenes on fever in persons who have previously laboured under disorder of the biliary system."

"Between this form and the true yellow fever of certain hot climates there is at least this specific difference, that in the latter the yellow colour of the skin is pathognomic and general, though perhaps not a universal symptom, while in the endemic fevers of this country it is a rare and accidental occurrence, arising from an accidental cause. There exists, probably, the same analogy between this form of fever and the true yellow fever, as between typhus attended with glandular swellings, and the plague."

Typhus fever is sometimes followed by *musæ volitantes*, or even by amaurosis, and in some rare instances by phlebitic ophthalmitis. Certainly no febrile disease with which we have been hitherto acquainted in this country is followed by such an inflammatory affection of the eye, as that which I am about to describe. I have known the disease which is called hay fever, followed by intermittent ophthalmia, of iritic character. Dr. Lawrie informs me that remittent fever in India is sometimes followed by corneitis, and sloughing of the cornea.

I shall now select, from the journals of the Glasgow Eye Infirmary, a few cases illustrative of the affection of the eye, which has appeared as a sequela of the remittent fever now prevailing. From the 8th August to the 31st October, when I finished my quarterly period of attendance, 36 cases of this description were taken on the list. The general subjects of the affection in question

have been from 17 to 20 years of age; but it has spared neither young children nor old people. The youngest out of the 36 was 18 months old; the oldest was 56 years. The general character of the disease has been partly amaurotic and partly inflammatory. In by far the greater number of cases the eyes attacked had been previously healthy, but in some instances they had suffered from other diseases, and in one case they were already in a great measure disorganized.

CASE I.—Amaurosis and ophthalmitis after remittent fever—treated by leeches, calomel and opium, belladonna, blisters, and quina—complete recovery.

No. 13185.—Aug. 8th, 1843. Margaret Spence, aged 12, was seized with remittent fever, which she calls influenza, nine weeks ago. Right eye became red three weeks ago. Conjunctiva still somewhat red; pupil dilated, and does not contract readily on exposure to light; vision of right eye so dim, that she does not see the eyes of a person sitting before her. Circumorbital pain. Pulse 108.

Hirud. vj. ad temp. dext.

R Subm. Hydr. gr. ij.; Pulv. Opii, gr. j.
M. ft. pulv. hor. som. sumend.

Cras mane Sulph. Magn. ʒss.

9th.—Less pain; vision rather better.

Cap. j. post sedes singulas liquidas.

24th.—Cap. Sulph. Quin. gr. j. ter indies.

Oct. 15th.—Says her eye is perfectly well.

Omit. remedia.

CASE II.—*Retinitis and amaurosis after remittent fever—complete cure by leeches, calomel and opium, blisters, and quina.*

No. 13186—Aug. 8th, 1843. Margaret Paterson, aged 11, had remittent fever in the end of June. Eight days ago, right eye appeared red. The conjunctiva and scleroticæ are moderately injected; the iris is of a green hue; the pupil somewhat dilated, and very sluggish; the retina retains merely a perception of light and shade. No pain of head; pulse 120; tongue clean.

Hirud. vj. ad temp. dextr.

R Subm. Hydr. gr. iv.; Pulv. Opii, gr. j.

Cap. pulv. j. o. n. tantum.

22d.—Right pupil not so much expanded as left. Vision improves slowly; is still most defective when she looks sinistrad.

25th.—Vision continues to improve.

Omit. pulv. Subm. Hydr. et Opii.

Cap. Sulph. Quin. gr. j. ter indies.

27th.—Still improves.

Sept. 1st.—Vision much improved.

3d.—Bowels confined.

Cap. Pulv. Jalap. Comp. gr. xv.

6th.—Cont. Quina.

12th.—Continues to improve.

20th.—Says her eye is quite well.

CASE III.—*Iritis after fever—treated with quina, leeches, and vesication.*

No. 13223—Aug. 26th, 1843. Catherine McDonald, aged 55, has been labouring under the epidemic fever now prevalent. Right eye affected with iritis. Iris discoloured; pupil hazy; vision dim; nocturnal pain in eyeball, preventing sleep. Pulse 96, small.

Belladon. ad palp. dextr.

Cap. Sulph. Quin. gr. ij. Svâ qq. horâ.

29th.—Pain not relieved.

Hirud. vj. ad palp. dextr. Cap. Ol. Ricini, ʒj. Hodie omit. Quina.

Sept. 1st.—Eye easier; vision clearer.

8th.—Vesicat. pone aur. dextr.

14th.—Much improved.

CASE IV.—*Ophthalmitis after fever—treated by venesection, leeches, calomel and opium, belladonna, vesication, and quina—muscæ volitantes left as a sequela.*

No. 13254—Sept. 7th, 1843. James Nairn, aged 18, had epidemic fever in July last. After twelve days had a crisis, but relapsed after other four days, with shiverings, and pain in the bowels. Eleven days ago symptoms of iritis affected right eye. Scleroticæ injected; iris, naturally hazel, of a darker colour than that of opposite eye; pupil contracted and irregular; sight so dim that he cannot read the large letters on the Infirmary card. Supra-orbital pain, increased during the night, and preventing sleep. Has applied four leeches, without relief.

Venesection. Belladon. ad palp. dextr.

Cap. pil. Subm. Hydr. gr. ij., et Opii, gr. ss. i. Svâ. qq. horâ.

8th.—Pain relieved; pupil somewhat dilated; vision rather clearer.

9th.—Hirud. vj. ad temp. dextr.

10th.—Gutta Sol. Nitr. Argent. (gr. x. ad Aq. ʒj.) ad ocul. dextr. Vesicat. pone aur. dextr.

12th.—Eye easier; pupil more dilated.

14th.—Much improved.

17th.—Mouth begins to be affected; eye much better.

Cap. pil. j. indies tantum.

20th.—A muscæ volitans before right eye. In other respects better.

25th.—Omit. pil. Cap. Sulph. Quin. gr. j. ter indies.

Oct. 6th.—Eye free from inflammation; still complains of muscæ volitantes before right eye.

24th.—Says that the vision of right eye is as clear as that of left, but he is still troubled with muscæ volitantes.

Omit. Quina.

CASE V. — *Epidemic fever — abortion — iritis — cured by belladonna, quina, and purgatives.*

No. 13260 — September 9th, 1843. Mary Quin, aged 29, was seized with epidemic fever about a month ago. This was followed by an abortion in the fourth month. Eyes have been affected with slight rheumatic iritis for twelve days. Pulse 96. Bowels regular.

Belladon. ad palpebras. Cap. Sulph. Quin. gr. j. octavā qq. horā.

11th. — Right pupil a little dilated, and vision of that eye somewhat clearer.

Cap. Pulv. Jalap. Comp. ʒss.

12th. — Right pupil more dilated.

14th. — Inflammation abates.

18th. — Rep. pulv. purgans.

CASE VI. — *Epidemic fever, followed by capsulitis of the crystalline and cornea.*

No. 13263 — September 10th, 1843. John Collins, aged 31, a travelling dealer in stone-ware, had the epidemic fever about six weeks ago. Eight days ago, when travelling by railway, supposed some particles of coke to have got into his right eye. Conjunctiva and sclerótica of that eye very slightly injected; iris of a lighter colour than that of opposite eye; both irides greenish; makes no complaint of left eye, the vision of which is good; right pupil natural in size; its motions limited and slow; vision of right eye so dim that with difficulty he tells one finger from another with it, when held close before him; pupil appears slightly muddy, and on concentrating the light upon it with a convex lens, a reddish wreath appears on the anterior crystalline capsule, just within the verge of the pupil; says that for two nights the pain was pretty severe in right eyeball. Pulse 84, small; tongue white.

Belladon. ad palp. dextr. Pulv. urg. ʒj.

11th. — Right pupil widely dilated; the red wreath is now situated half way between the centre and the circumference of the pupil; a number of minute spots visible on the internal surface of the cornea, especially towards its lower edge; vision considerably clearer.

Cap. Pil. Hydrarg. j. m. et v.

CASE VII. — *Epidemic fever, followed by ophthalmia of catarrho-rheumatic character, relieved by venesection, belladonna, purgatives, and calomel and opium.*

No. 13282 — September 19th, 1843. Ann Morison, aged 41, had epidemic fever in July, since when has been constantly troubled with pain in left side of head. Left eye affected with ophthalmia of catarrho-rheumatic character. Pulse 72; tongue foul;

bowels costive; no sleep, from the hemicrania. Applied four leeches with some relief.

Belladon. ad palp. sinistr.; Venesection. Pulv. Purg. ʒj.

20th. — Blood buffy; pain much relieved; pupil irregularly expanded.

CASE XII.—*Epidemic fever; three relapses followed by amaurosis and ophthalmitis; symptoms yield to quina, leeches, and mercury.*

No. 13346—16th October, 1843. John Harvey, weaver, a.t. 44, had epidemic fever twelve weeks ago. Had three relapses. Found vision of left eye to become dim about a fortnight ago. It is now so deficient that he merely perceives light and shade with it. Four days ago the eye began to get red. Sclerotica much injected; a narrow whitish ring between sclerotica and cornea; cornea

rather hazy; iris greenish; pupil contracted, irregular, and very hazy. Supra-ocular pain, increased during the night, and at that time preceded by rigors. Much lachrymation. *Muscae volitantes*. Pulse 72; bowels regular. Thinks the affection of his eye arose from his going into his cold shop to work.

CASE XIII.—*Ophthalmitis after fever: being neglected, ends in synechia posterior, and almost total loss of sight; slow improvement under the use of quina and calomel.*

No. 13355—18th October, 1843. Bridget Carey, æt. 50, had epidemic fever four months ago. Three months ago, sight began to fail. Both pupils are irregular, and the lenses very hazy. Vision, especially of the left eye, nearly limited to a perception of light and shade. Gropes like an amaurotic, and has a most melancholy expression. To relieve the burning heat of eyes, poulticed them for two months. This has produced entropium of each lower eyelid. Pain in the temples, especially during the night. Tongue clean; bowels bound. Back of pharynx ulcerated. Says the throat has been sore since before taking the fever. Has used only purgatives, such as salts and castor oil.

30th.—Pupil widely dilated.

Abluce Belladon.

Nov. 1st.—Continues to improve.

CASE XV.—*Severe ophthalmitis after remittent fever; relieved by venesection and mercury.*

No. 13378—28th October, 1843. Hugh Lecch, æt. 26, was seized with remittent fever about eight weeks ago. First attack lasted about ten days; the remission three days; and the second attack seven days. During his convalescence, was sleeping in a very uncomfortable place, and much exposed to cold. On the morning of the 25th, awoke with great pain in right eye. The sclerótica is intensely red, the iris has assumed a green colour, the cornea is slightly hazy, and the pupil very much so; it is considerably contracted, and the vision of the eye is limited to a perception of light and shade. Pulse 108. Tongue white. Underwent no treatment for the fever.

CASE XVI.—*Remittent fever; abortion; ophthalmitis: relieved by leeching and mercury.*

No. 13379—28th October, 1843. Flora Reynolds, æt. 22, was seized with epidemic fever six weeks ago. Says the attack lasted two weeks, and that she had no relapse. Five weeks ago had a miscarriage at the third month, with excessive discharge. Menstruated a week ago, and more profusely than common. Says her feet and legs became dropsical during her convalescence. Was sleeping in an apartment with broken windows, and ten days ago was attacked with pain in left eye, which now presents the usual symptoms of ophthalmitis post febre, the sclerótica being injected, the iris discoloured, and vision very dim. No sleep, from hemicrania; pulse 84; tongue clean; bowels regular.

octavâ qq. horâ.

REMARKS.—The cases above related may serve to give an idea of the affection of the eyes, which has in so many instances followed the fever now prevailing, and of the treatment which I have employed for it. I have generally called the disease *ophthalmia post febre*, but perhaps the appellation of *ophthalmitis postfebrilis* is more correct.

Statistics.—The following are a few statistical facts, which may be worthy of notice:—

Out of the 36 cases which I treated in August, September, and October, 27 occurred in females, and only 9 in males.

The following were the ages of the 36 patients:—Below ten, 2; from ten to twenty, 17; from twenty to thirty, 9; from thirty to forty, 2; from forty to fifty, 3; from fifty to sixty, 3.

In eighteen of the cases, the right eye only was affected; in ten, the left only; and in eight, both eyes, either together or consecutively.

The attack of ophthalmitis occurred at various periods from three to sixteen weeks from the commencement of the fever. In several cases it came on about two weeks after convalescence from the relapse, but generally somewhat later.

The very same disease of the eye occurred after the Dublin epidemic of 1826, and was described by Mr. Hewson*, Dr. Reid†, Dr. Jacob‡, and Mr. Wallace§. The last mentioned author has remarked the greater liability of the right eye to be affected than the left. "Of forty cases," says he, "which I have noted, there were only four who had the disease in the left eye, and only two had it in both." Out of the ten cases in which it happened to me to observe it in the left eye, seven were females. The attack is generally traced to a draught of cold air during the night; it is probably the eye which is exposed which becomes affected, while that belonging to the side on which the patient rests, escapes.

Dr. Jacob has remarked, that the disease occurs much more frequently in young than in old persons. Of thirty cases in which he noted the ages, three only were above 25. He also met with it more frequently in females than males. In the majority of the cases seen by him, the inflammation made its appearance within six weeks or two months after recovery from the fever; in some in-

* Observations on the History and Treatment of the Ophthalmia accompanying the Secondary Forms of Lues Venerea, pp. 34, 109. London, 1814.

† Transactions of the Association, &c. Vol. v. p. 294.

‡ Ib. p. 468.

§ Medico-Chirurgical Transactions, Vol. xiv. p. 286. London, 1828.

stances, however, it appeared before the patients left the hospital, and in others not for four, five, or even eight months,

Symptoms.—The character of the disease appears to be, in the first instance, that of congestion, followed by inflammation of the internal parts of the eye, and especially of the retina, producing great imperfection of sight. This is succeeded by evident inflammation of the iris and sclerotica; the disease extends to the capsule of the lens, and sometimes to the lining membrane of the cornea; there can be little doubt but that the choroid is also inflamed; while the conjunctiva remains in general but slightly affected.

The part which the sclerotica takes in the disease is plain enough, from the intense injection of the blood-vessels which lie on its surface, and which, derived from the muscular and anterior ciliary arteries, are seen running in radii towards the cornea. The change of colour in the iris, the contracted state of the pupil, and the tags of adhesion between the edge of the pupil and the capsule of the lens, show the part which the iris takes in the disease. The internal membrane of the cornea, and the anterior crystalline capsule, especially the latter, are extremely muddy, shewing their participation in the inflammation. The whole walls of the aqueous cell seem in some cases as if coated with a thin layer of lymph, of a yellowish-green colour. The great deficiency of sight is not explicable from the mere muddiness of these parts, and is, besides, often the earliest symptom of the disease, shewing an affection of the retina. At an early period, the pupil is sometimes dilated, and does not become contracted till the inflammation embraces the iris. If not promptly combated by the appropriate remedies, the cornea and sclerotica become preternaturally flexible under the pressure of the finger, showing that the disease has extended to the vitreous body. In one case I found the cornea very flexible in the amaurotic stage, before there was any appearance of inflammation.

At the commencement, it is possible that only the central artery of the retina, and the vasa longa of the hyaloid, may be affected. The irritation and injection speedily spread, in all likelihood, to the short, as well as to the long ciliaries; to the vessels of the ciliary processes, and of the zonula Zinnii; to the vasa brevia of the hyaloid, the vessels of the anterior crystalline capsule, and those of the lining membrane of the cornea; and to the sclerotic network.

The lacrymation is very considerable, and seems to be connected, not so much with the state of the conjunctiva, as with the pain in the interior of the eye-ball. The severe pain in and round the eye, aggravated during the night, is exactly similar to what attends

rheumatic and syphilitic ophthalmia, and may partly be ascribed to the pressure exercised upon the ciliary nerves within the eye, by the inflamed parts, partly regarded as a direct neuralgic affection, such as we often meet with in the six branches of the fifth nerve which emerge from the orbit, when there is no evident inflammation present. It is, in general, only after the iris and sclerotica have taken part in the disease, that the patient complains of the ocular and circum-orbital pain. So long as the disease is confined to the retina there is little or no pain. Hence the patient is less alarmed than he should be, by the mere dimness of sight, which, indeed, from only one eye being generally affected, may scarcely attract his attention. Even photopsia, in the early stage, is not much complained of; in the last stage, muscæ volitantes form a constant symptom.

Although, in by far the greater number of cases, all the textures of the eye suffer in this disease, on which account it may be designated as an *ophthalmitis*, it sometimes happens that the inflammation is confined to one or two textures only. Thus in Case 6 the anterior crystalline capsule and the lining membrane of the cornea only were visibly affected with inflammation.

The pulse varies from 84 to 120. Frequently rigors occur. The tongue is generally clean and moist. The pain entirely prevents sleep.

Diagnosis.—The present disease is much more extensive, in respect to the number of textures affected, and much more intensive, in so far as the morbid action which is at work is concerned, than rheumatic ophthalmia, or rheumatic iritis; to which, however, in many particulars it bears a resemblance. Yet, along with postfebrile ophthalmitis, we have neither the bounding pulse, the hot skin, nor the white and loaded tongue, which attend inflammation of the sclerotica and iris from mere exposure to cold. Neither is the blood drawn from a vein so buffy. The pain is not less distressing. Vision is much sooner, and much more seriously involved.

Mr. Wallace considers this affection of the eye as bearing so very striking a resemblance to syphilitic ophthalmia, that the one cannot be distinguished from the other without particular attention to the history of the case. The absence of the tawny-reddish border which surrounds the pupillary margin of the iris, and there being tubercles on the iris in postfebrile ophthalmitis, will serve to distinguish the two diseases.

The acuteness of the present disease will discriminate it from scrofulous iritis, to which, particularly in the appearance of the lens, it bears considerable resemblance, as

well as in the degree in which the retina is affected.

In some instances, postfebrile ophthalmitis bears a considerable resemblance to catarrho-rheumatic ophthalmia. Onyx, so frequent in the latter disease, I have not witnessed in the former. In one case I observed a considerable portion of the conjunctiva corneæ ulcerated, but never the ulcer which affects the proper substance of the cornea, and which is so characteristic of the catarrho-rheumatic disease.

The disease to which postfebrile ophthalmitis bears the nearest resemblance is sympathetic ophthalmitis; which results so frequently from incised and lacerated wounds of the edge of the cornea and sclerotica, and consequently of the annulus albidus of the opposite eye. The cause of the great similarity is, that in both cases the inflammation commences in the retina, advances to the iris, embraces all the internal textures of the eyeball, and ends, if neglected, in closure of the pupil, opacity of the crystalline, softening of the globe, and insensibility to light. The slightest inquiry into the history of the case will in either instance elucidate the origin of the affection.

Stages.—Mr. Wallace has described this disease as presenting two stages; the first amaurotic, and the second inflammatory. The cases above detailed sufficiently illustrate the accuracy of Mr. Wallace's description. "During the first stage," says he, "there exist amaurotic symptoms alone; and in the second stage, to the amaurotic symptoms are superadded the symptoms of inflammation. The length of time that the amaurotic symptoms exist before the occurrence of external redness, or of the visible symptoms of inflammation, is extremely uncertain, as also the period after fever at which the amaurotic symptoms commence. On many occasions the amaurotic symptoms, particularly a slight dimness of vision, with *muscæ volitantes*, have commenced at or even before the time of convalescence from fever, and yet the inflammatory stage has not supervened for weeks or even months; while on other occasions the dimness of vision has not commenced for several days, weeks, or even months, after the febrile attack, and has then been immediately followed by the symptoms of inflammation. It is to be particularly observed that I have never seen a case in which, upon strict inquiry, amaurotic symptoms, more or less strongly marked, have not preceded the inflammatory symptoms. This is, in fact, one of the most remarkable characters of the disease. It is also to be noticed that a similar distinction of symptoms is observable during amendment, for it uniformly happens that the inflammatory symptoms subside a longer or shorter time before the amaurotic

symptoms disappear, and often before they are diminished in severity."

The first and second cases, which I have related, bore, not merely at the commencement, but all along, much more the aspect of amaurosis than of ophthalmitis. In one case which I saw, the patient was suddenly struck blind of the affected eye. In another case, already referred to, along with amaurotic symptoms, the cornea had become flexible, and, no longer apprehensive of inflammation supervening, I had commenced the use of quina and blisters, when suddenly pain and redness set in. I have met with several cases in which, for days, the principal symptoms have been pain in and round the eye, and dimness of sight. In other cases, there has been redness of the eye from the very commencement.

Predisposing and exciting causes.—That an opportunity is left for the disease of the eye by the fever is plain; there may even be grounds for suspecting that the fever may have left the circulating fluids in an altered state, favourable for the production of the local complaint. However this may be, the affection of the eye is generally traceable to some exciting cause, and especially to cold. Sleeping in an apartment with broken windows, working in a cold damp shop, and washing the head with cold water, are mentioned in the cases as exciting causes. Using the eyes too early in sewing is another.

Prognosis.—The recovery is tedious. In the majority of cases, two months of uninterrupted and careful treatment has been necessary to effect a cure. That the disease, without any treatment, will wear itself out, is true; but the eyes will be left, as in Case XIII., useless, from the contracted and adherent state of the pupil, and the amaurotic condition of the retina. If trifled with, the cure will be imperfect; *synechia posterior*, *muscæ volitantes*, and other irremediable sequelæ, remaining. If taken early, and treated vigorously, a complete cure may be prognosticated. Recovery is much more speedy and complete in young subjects; in adults it is more tedious.

TREATMENT.—I. *Depletion.*—The wan appearance of many of the patients, the smallness of their pulse, and the state of general debility in which they are, might tend to deter from a use of the lancet. I am satisfied, however, that we can rarely, with safety, dispense with this remedy. The blood, drawn from a vein, is only in a few cases buffy. Often it is difficult, from syncope coming on, to obtain more than a few ounces from the arm. When this is the case, leeches to the temples and round the eyes must be had recourse to.

If depletion is neglected, the recovery is very slow and uncertain; adhesions form, and cannot be got rid of, and vision continues

imperfect. We must not be regulated by the pain alone in taking away blood. Nothing relieves the pain so strikingly and effectually as venesection; but the state of the eye, independently of the pain, demands the taking away of blood. We should not even wait for the inflammatory stage of the disease, but relieve the congestion, on which the amaurotic symptoms depend, by the employment of depletion.

Some cases, especially in children, I have trusted to leeching; but in adults venesection is almost always necessary. I have not used arteriotomy, nor cupping, but have no doubt of their efficacy.

2. *Purgatives*.—The tongue being generally clean, and the bowels regular, there seems to be little demand for purgatives. At the same time, I have found them of considerable use in the course of the treatment. Sulphate of magnesia, castor-oil, and compound powder of jalap, are those I have most employed.

3. *Mercury*.—I am decidedly of opinion that the safest and the most effectual plan of cure embraces the use of calomel with opium, exactly as in the treatment of rheumatic or syphilitic iritis. This view of the matter is confirmed by the testimony of Mr. Hewson, who seems to have trusted to opening the temporal artery, and giving a dose of three grains of calomel with half a grain of opium each night. Dr. Jacob, also, found the use of mercury so certain and decisive in this affection of the eye, that he trusted to it almost exclusively. He gave two grains of calomel and a quarter of a grain of opium thrice a-day. The mouth should be made sore, but not too suddenly, lest we be obliged to omit the medicine prematurely.

4. *Belladonna*.—The dilatation of the pupil is an essential part of the treatment. This is to be effected by liberally smearing the eyelids and eyebrow with the moistened extract of belladonna, morning and evening; directing the patient to renew its activity from time to time, by re-moistening it with his finger dipped in water.

5. *Counter-irritation*.—Considerable benefit is derived from blisters to the temples and behind the ears, after due employment of depletion. They aid in removing the pain, lessening the inflammation, and recalling the power of vision.

6. *Cinchona*.—Mr. Wallace has keenly advocated the supremacy of cinchona as a cure for this affection of the eye. He thinks it has a specific influence over the disease; recommends it both when the patient is weak and seems to demand tonics, and when he is in full health; maintains the incurability of the disease by mercury; and is decidedly of opinion that there must exist some source of error in Mr. Hewson's account of the cases cured by this medicine.

"When I commenced the use of bark in this disease," says Mr. Wallace, "I did not venture to employ it when the inflammatory symptoms were very severe, without preceding its administration by bleeding and purging. But latterly, whenever a case has presented itself, I have prescribed the bark alone, or simply with such medicines as were suited to the regulation of the bowels; and with the most decidedly good effects. Indeed, I have thought that the abstraction of blood has, on some occasions, considerably retarded the cure; yet cases may occur in which bleeding and purging will be necessary."

I have not employed cinchona bark in powder, but the trials I have made of sulphate of quina have not led me to adopt any very high opinion of its efficacy in this disease. Some of the milder cases have yielded, in a great measure, to the combination of calomel and quina, such as Case 9. Case 5 was much benefited by quina. In Case 10 it acted very slowly and imperfectly. On the whole, I feel indisposed to trust to this remedy; and on this point I find my views corroborated by the experience of Dr. Jacob. "In two cases which I met with," says he, "after the inflammation had subsided, and in which vision was as much impaired as if no remedies had been adopted, bark, in powder, had been administered for ten days. I gave trial to the sulphate of quinine myself in four well-marked cases for eight days, but finding no relief, had recourse to mercury, which effected a cure in the usual time."

I shall not unnecessarily extend this report by commenting on the advantages to be derived from regulating the diet of the patient in this disease, and protecting him from cold; on the utility of warm fomentations, and anodyne frictions; nor on the problematical effects of such internal remedies as tartar emetic, colchicum, or turpentine, which I have not tried.

REMOVAL OF A DROPSICAL OVARIUM.

By GEORGE SOUTHAM,

Surgeon to the Salford and Pendleton Royal Dispensary, Manchester.

[Concluded from p. 204.]

(For the London Medical Gazette.)

—
WITH respect to some objections urged against the operation, as I believe that they are more imaginary than real, it may be well to offer a few remarks upon them.

It has been alleged, that although ovarian tumors ultimately prove fatal,

yet, by the interposition of remedial means, the patient's life may be prolonged for several years in tolerable comfort, whilst there is a great probability of death immediately following extirpation. It is no doubt true that individuals have lived many years in comparative ease with this disease, but I am inclined to think they bear a very small proportion to those who, from an early period, are in a constant state of suffering, which often causes death in a very few years, and not unfrequently in twelve or eighteen months.*

Dr. Bright has given the history of seven cases, which show that the disease if left to itself destroys life in about three years from the time it is first detected; an average by no means overstated, when we consider the premature deaths it occasions by impeding

parturition. References to eighteen such cases, comprehending thirty-eight lives, are given by Dr. Merriman in the 10th volume of the *Medico-Chirurg. Transactions*, from which it appears nine women died; three recovered imperfectly, six perfectly. Of the children, sixteen were still born; four were alive; so that the lives actually preserved amounted to only twelve, the deaths to twenty-six.†

It is very doubtful whether most of the remedies proposed to retard the progress of the complaint have not rather accelerated its fatal termination; and from the following table, it will be seen that paracentesis, which is generally considered the most effectual palliative, not only affords a very temporary relief, but is by no means unattended with danger.

Table of twenty cases of Ovarian Disease in which Paracentesis was performed.

Those marked (¹) occurred in the practice of Dr. Bright. The five marked (²) are recorded by Dr. Barlow, in the 4th volume of the *Provincial Medical Transactions*. The others were under my own care.

From Dr. Ashwell's summary of Obstetric Cases admitted into Guy's Hospital, it appears that of eleven cases of hydrops ovarii, seven were tapped; three of which were unsuccessful. He does not state how often they were individually tapped. Reports, 1837-8.

* Vide Bright's Records of Ovarian Tumors, Guy's Hospital Reports, 1838. Dr. Seymour relates the particulars of a case where the disease appears to have run its course in six months.—

Illustrations of Diseases of the Ovaria, 1830, p. 67, 68.

† Synopsis of Difficult Parturition, 4th Edition, p. 62.

Thus, fourteen died within nine months after the first operation, four of whom survived it only a few days. Of the remaining six, two died in eighteen months, and four lived for periods varying from four to nearly nine years.

It further appears that paracentesis does not prolong life on an average for more than eighteen months and nineteen days; and that one in five dies from the effects of the first operation. Another fact to be gathered from the table is, that the peritoneum being more prone to inflammatory action in some persons than in others, repeated tapplings, instead of proving barriers to extirpation, show that (other circumstances being favourable) there is much less risk of inflammation following the operation.

The disease, it is said, frequently assumes a malignant character, consequently no lasting benefit will result from the operation. Indeed, Dr. Bright states, "it is truly a malignant disease; and though it usually assumes one, and that a milder modification, in preference to the rest, is not unfrequently found degenerating into the worst and most destructive forms of the fungous and cerebriform cancer; and it undergoes those changes by such insensible degrees, that it is impossible to draw the line, and deny a malignant character to one, while we grant it to the others."

Some of his cases certainly prove that the ovary may be affected with malignant disease, in common with the other organs of the body; but if the term malignant is to be limited to cancer, medullary sarcoma, and fungus hæmatodes, they afford no more proof that the true dropsical ovarium ever partakes of any of those affections, than that the presence of tubercles in the ovaries shows the disease to be of a serofulous nature, as some have supposed. The mamma is the most frequent seat of schirrus; yet encysted tumors may be developed in its structure, and remain for several years, or even for life, without degenerating into any of the forms of that disease.

The analogy between dropsical cysts and the local origin of carcinoma, which Dr. Hodgkin* first discovered to consist in the presence of a serous membrane having a cystiform arrangement, affords no proof of their identity, since the recent researches of Schwann,

Müller, and others, show that not only are all abnormal growths formed from cysts or cells, but that the different structures of the body have a similar origin. We cannot, therefore, adopt what appears to be the revival of an old theory, which referred the formation of schirrus to the previous existence of vesicles having the nature of hydatids*, but must look for its element in a perversion of the nutritive and secreting functions of the body.

The only foundation for attributing malignancy to the encysted ovarian disease, appears to consist in the presence of the solid masses sometimes forming part of the tumor, or growing from the internal surface of the cysts, which on a superficial inspection not unfrequently resemble the semitransparent and fibrous structure of schirrus, or the cerebriform and fungoid appearance of medullary sarcoma; but any further they do not appear to assimilate.

The peculiar appearance of the countenance, the sharp lancinating pains, and other general conditions of the patient which denote the existence of schirrus, seldom occur in persons suffering from the true ovarian disease. The ulcerated surfaces of the tumor present no hard, ragged, and everted edges; the indications of hæmorrhage having previously existed are wanting. The fluid part bears a large proportion to the rest of the structure, and instead of assuming the character of an offensive ichorous discharge, when of a purulent nature, it has the appearance of ordinary pus. Cysts have been frequently found after death connected with the ovary, which had not been detected during life, and there are several authenticated cases of extremely large tumors, with equal and smooth surfaces, having existed for many years without affecting the healthy functions of the body, which generally suffer more or less where there is any tendency to malignant action.

The disorganization, therefore, occasionally met with in ovarian tumors must be referred to causes having a local origin, probably to inflammatory action, produced from pressure and other irritating circumstances. It is well known that encysted tumors, when seized with inflammation, cannot,

* Med. Chr. Transactions, Vol. 15.

* Barron on Tuberculous Diseases.

from their low degree of vitality, long resist its influence.

As in diseased states of the system inflammation frequently takes on some specific action, it is not unlikely that, when it attacks morbid growths, effects may be produced, which, though not exactly presenting the appearances of healthy inflammatory action, are analogous to its suppurative and ulcerative stages, or to that peculiar alteration of the tissues called *ramollissement*.

Having carefully examined several specimens of dropsical ovaria, I am inclined to agree with Drs. Hunter and Burns*, that they never present a truly scirrhus character; on the contrary, that they generally consist of simple cysts, or partake of what is called cystic sarcoma†, for the development of which the peculiar structure of the ovary appears highly favourable.

The far greater size which the disease attains, compared with similar affections in other parts of the body, depends on a variety of circumstances; the most obvious of which are, the position of the ovaries in the abdomen being free from all pressure or restraint likely to limit their development; the abundant supply of blood which the parts periodically receive, and the natural disposition of the generative organs to obey a stimulus which requires an increased supply of nutritive matter, and gives rise to a proportionally rapid growth‡.

I lately examined the body of a female who had died from what was thought to be a dropsical ovarium. The tumor, however, originated in the fallopian tube, and was formed of two cysts: one contained upwards of three gallons of fluid, the other about two. On the internal surface of each cyst, in the most depending situations, there were several patches of solid matter, apparently of recent formation; none of them were larger than a crown-piece, and in a few instances they had coalesced. The ovaries and other organs of the body were perfectly sound. This case resembles several described by Dr. Baillie and others as *hydrops tubalis*. They evidently consist of adventitious cysts, and do not differ from similar ones sometimes found in the ovaries,

which have been erroneously supposed to be merely enlarged Graafian vesicles*.

Since the disease rarely leads to a speedily fatal termination, we have seldom opportunities of examining its earliest conditions; but from the history of protracted cases, it would appear that one or two cysts frequently exist for several years before the solid matter is developed, and that the progress of the complaint is often influenced by the quantity and rapidity with which the latter has been secreted.

The proportion which the solid mass bears to the whole tumor forms an important feature in recommending extirpation. *Solidity alone* must be regarded with caution in determining upon the propriety of the operation, as it generally indicates malignancy, or uterine disease. The presence of fluid being one of the essentials of the true ovarian disease, extirpation ought never to be attempted where it is not detected.

In arguing for the non-malignancy of the ovarian disease, I do not deny that encysted tumors may occasionally occur in connection with some of the varieties of scirrhus. They are sometimes combined in the testicle, but more frequently they occur in parts at a distance from each other. Not many days since, I saw a man suffering from cancer of the lip, who had a tumor near the nose presenting all the characters of cystic sarcoma, which had existed many years before the other disease appeared. I have notes of a similar case where the cancer was removed, and though the patient lived upwards of three years, the sarcomatous tumor never assumed a malignant appearance.

The simultaneous occurrence of these diseases, then, cannot be regarded as necessary conditions of each other, but merely as indications in the system of a tendency to develop morbid growths.

With respect to the malignant affections of the ovaries, it has been customary to class many diseases with them which have not the least analogy.

"It is impossible to conceive," says Dr. Seymour, "any signification more vague than the sense in which the term scirrhus is used, when applied to diseases of the ovarium. If taken in the comprehensive meaning in which many au-

* System of Midwifery, p. 136.

† The firm or sarcomatous part of a diseased ovary was regarded by Mr. Abernethy as an excellent specimen of the structure of this disease.

* Cruveilhier, Anatomie Pathologique, cinq livraisons.

thors have employed it, it represents equally the degeneration of the ovarium by age, and the enlargement of the ovarium by the deposition of any solid structure; and is often applied to that form of ovarian disease in which a portion of the tumor is solid, and a portion made up of cysts filled with secretions of various consistence.*

Malignant disease of the ovary may generally be easily recognised by the mammae or other organs being more or less implicated, and by the general cachectic condition of the constitution. The tumor is developed with much greater rapidity than the ordinary ovarian disease, presents an uneven surface, and consists principally of solid matter.

Much has been said respecting the proneness of both ovaries to be diseased. I have carefully examined the records of 29 cases of true dropsical ovaria, and found that there were but two in which the opposite ovary presented a *decidedly* abnormal character*. Where, however, the disease was malignant, both were affected in three cases out of four. As an objection, then, to extirpation, the complication is scarcely worthy of notice, seldom occurring where the operation would be considered justifiable.

I may here advert to an affection occasionally attacking the testicle, identical in structure to encysted disease of the ovary, and usually, but erroneously, designated hydatid testicle. This disease, like that of the ovary, is unaccompanied by any constitutional taint, being entirely local; and experience proves that it has several times been removed without the patients suffering any relapse.

Though several successful cases of extirpation have recently been published, many surgeons still regard the operation as too dangerous to be admitted into the routine of practice. To exhibit the amount of danger, Dr. Forbes has favoured us with the statistics of the operation, which are here chiefly noticed on account of their inaccuracy. He gives two tables, the first of which he says "displays those cases in which the diseased ovarium was actually extirpated," from which it appears that of 19 cases, 6 were fatal.

* Removal of one ovary does not prevent the female becoming pregnant, for Dr. Chrysmar states that his patient, who was alive eight years after the operation, had in the interval given birth to a living child.

This statement is given in the October number of his Review, and might be expected to contain the actual state of experience to within a few weeks of its publication. But what is the result? Mr. Walne's second successful case is omitted, although it was announced in the *MEDICAL GAZETTE* nearly three months previous to the publication of Dr. Forbes's tables; whilst among the fatal cases he has included one of uterine tubercle recorded by Dr. Clay*. With these corrections, the statistics previous to October last would be five fatal cases out of 19, or nearly 1 in 4 of those actually extirpated; an average which suffers no diminution from the four cases since recorded, one only of which (Mr. A. Key's) was fatal. Those, then, who test the propriety of an operation by statistics, must sanction this one. Few surgeons hesitate to perform amputation of the thigh, though Mr. Phillips, who has paid great attention to this branch of surgical practice, states that nearly two out of five die†. In the Parisian hospitals, the operation for hernia proves fatal in four cases out of seven‡, and in London the result is scarcely more favourable§. If a correct system of reporting was honestly carried out in the London and provincial hospitals, I believe lithotomy would not be found so successful as is generally stated—not to mention that it sometimes requires repetition||.

With regard to the statistics of the operation, much reliance cannot be placed on them, until the cases are more numerous, and surgeons better agreed as to the nature of those warranting extirpation. Mr. Walne appears to select those only where the symptoms indicate few or no adhesions. Dr. Clay says, that "neither extent of adhesions, size of tumor, ascitic deposit, worn-down

* In describing the disease, Dr. Clay remarks that it "presented very different appearances to encysted ovarian tumors; it was of a bright pink colour, hard as a piece of boiled liver, and composed of numerous small lobes with acute edges, similar to the lobes of the liver." * * * "There was but a small portion of the neck of the uterus and the os uteri that was not amalgamated with the substance of the tumor."—*Cases of Peritoneal Section*, p. 17.

† *MEDICAL GAZETTE*, Vol. i. 1840-1.
‡ *Gaz. Méd. de Paris*, and *Edin. Med. Journ.* Oct. 1843.

§ Of 18 cases operated on in Guy's Hospital, 9 were fatal.—See Mr. Poland's Report.

|| Mr. B. Cooper has operated three times on the same subject. Sir A. Cooper twice, if not a third time. Mr. Martinenu and Mr. Rigby have both operated twice.—*Guy's Hospital Reports*, 1843.

constitution, nor peritoneal inflammation, should prevent extirpation being performed." Having witnessed the operations on which this statement is founded, I can bear testimony to the amount of adhesions that may be overcome without occasioning any drawback to the patient's recovery. It must, however, be recollected, that the individuals were advanced in life, when inflammation is less likely to ensue, and that the adhesions, though extensive, were limited to the abdominal parietes, or to a few band-like attachments to the viscera. From the particulars of the fatal cases recorded by Dr. Chrysmar and Mr. Lizars, it appears doubtful whether the operation ought to be proceeded with when the diseased mass is found adhering to the viscera to any extent. I say found, because, before an exploratory incision has been made, we possess no means, except from the presence of ascitic fluid, which does not always exist, and mobility of the tumor, of ascertaining whether the connections of the disease will admit of its removal. Dr. Bright states, that when parietal adhesions are present, a slight crepitus, or the crackling feel of new leather, may be distinguished by making the parietes move gently over the tumor. This, I believe, depends on a small quantity of fluid between the adhesions, for when ascitic fluid has been absent I have not been able to detect it, though very extensive adhesions have been afterwards found.

The operation is perfectly justifiable when the patient's sufferings are such as to make life a burden to her; when the symptoms of structural lesion of any important organs are absent; and when the constitution is suffering merely from functional derangement consequent upon pressure of the tumor on the neighbouring parts. On the contrary, it ought not to be attempted when the well-known characteristics of malignant action are present; when the tumor is solid, uneven, and has been of rapid growth; when the glands in the vicinity are enlarged, and hard knots can be felt in different parts of the abdomen, or when there is distinct evidence of other organs being similarly implicated. Still less should it be undertaken until the surgeon, by varied and repeated examinations, is convinced of the existence of the disease. Nor must the rules which direct us as to

the propriety of operating in other diseases, respecting the condition of the sexual organs, and the fitness of the patient's constitution to undergo so severe an operation, be overlooked. Considering that extirpation of the ovary is still in its infancy, there is every probability that as our experience increases it will, under proper restrictions, prove as successful as lithotomy. The surgeon will be thus enabled to restore to health individuals who must otherwise have dragged on a miserable existence for a considerable period. A glorious monument will be raised to the healing art through the improvement of surgical knowledge; and that boldness of surgical energy, which the timid were but too ready prematurely to condemn, will be ultimately sanctioned by an enlightened and applauding profession.

CONTRIBUTIONS
TO
ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 212.]

Hermaphroditism; a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

DURING the winter sessions of the years mentioned in the title, I composed very hastily the memoir which follows these remarks, and which was read to the Royal Society at various times: the view adopted in the memoir I admitted then, and still admit, to be mainly theoretical; or rather, I may say, "in a sense theoretical," for essentially the theory is based on induction from a wide range of facts and observation, and on analogies of a striking and forcible kind. The "theory," however, has been objected to, and reasons have been assigned for its inadequacy to explain the phenomena it was presumed to embrace, by a gentleman of great learning, patience, and candour, Dr. Simson, author of an excellent article on hermaphroditism in the *Encyclopædia of Anatomy and Physiology*.

My object in the few remarks I am about to prefix to the memoir is briefly to reply to Dr. Simson's objections in the same spirit as his were brought forward; and as neither of us are the

claimants of any peculiar discoveries in the matter of hermaphroditism, but simply aim at the thorough investigation of those theories which have been proposed in explanation of the phenomena, (the general insufficiency of which I, with Dr. Simson, willingly concede,) there ought not to occur any asperity in the remarks, concealment of discordant facts, nor unwillingness on my part to admit the theory to be as worthless as all its predecessors and successors, provided it really prove so.

A paper read by M. Duncril to the French Academy first attracted my attention, whilst yet a student, to the doctrines of transcendental or philosophic anatomy: from this paper, or in some other way, I first learned that "the doctrine" that the "cranial bones were only vertebræ, cranial vertebræ," had been propounded by a learned physician, J. J. Frank; that he seemed to have borrowed from, or to have been anticipated by, Goethe; and Goethe by Newton. But it was not until the winter 1821, that after many, very many, conversations with the illustrious savans of the French capital—the elder Geoffroy, M. de Blainville (whose lectures I carefully attended), Baron Cuvier, and once with M. Oken, and Serres—that I learned the full extent to which some at least of these distinguished men were disposed to carry the transcendental theories of the German school. The elder Geoffroy in particular, himself not an anatomist, slowly drew after him, notwithstanding, the more practical men, the best anatomists of the capital; who finding themselves *unable* to stem the torrent, if I may so say, of idealism with which M. Geoffroy had possessed all minds, reluctantly and with much hesitation gave way to that doctrine which they could neither refute nor arrest. But the theories proposed to explain the development of the respiratory organs (these being the organs which chiefly engaged his attention at that moment), by the elder Geoffroy, appeared to me even then (1821) unsatisfactory, and even contradictory; and on my return to Britain, I ventured to propose in the course of my lectures on comparative anatomy, delivered during the summer sessions of 1825, 1826, and 1827, the theory of "type," not as contradictory of that of unity of organization (which it in no shape is), but in opposition to that doctrine which maintained that the re-

spiratory organs are at *first* in the embryo not only of one kind, but even "neuter as regards function;" that a pulmonary apparatus might be and was converted into a branchial set of organs; that organs might be converted into each other; that the hyoid bones were ribs, &c. To all these doctrines I made this forcible objection, namely, "that there exist animals with both lungs and gills; that the trachea and bronchial tubes, if found at all in animals whose breathing was aquatic, could only exist in them in a rudimentary condition, and could not be converted into other active organs of breathing; that the air-bladder in fishes was simply a rudimentary lung, and that the hyoid bones in man were merely rudimentary branchial arches; finally, I proposed the theory that in the embryo of all the vertebrata the type of the respiratory organs was double—at once aerial and aquatic, pulmonary and branchial. I have frequently been told that the same objection had been repeatedly made in Paris to M. Geoffroy himself; my personal esteem for my distinguished friend always prevented me speaking on the matter to him, at least with any view towards controverting his theory. But I well remember that a gentleman now ranking high as a philosopher, and who did me the honour to attend some of my lectures on comparative anatomy, asked me why I did not attempt to prove the theory by an appeal to the structure of the embryo of many animals, in some one or other of which I might happily stumble on the *direct proof* of the theory: and until this were shewn he felt disposed to view the whole doctrine as merely a theory, or hypothesis; an assumption, in fact, adopted to explain readily certain phenomena otherwise inexplicable. The same objection, if objection it can be called, had of course occurred to myself; it could not well be otherwise; an objection, similar in all respects, has been made by Dr. Simson to my theory of hermaphroditism. The objection, however, as it turned out, proved to be more apparent than real: that animals now live in whom both sets or organs *co-exist* was beyond all doubt, and therefore in them all the type is double; that in the adult animal, even in man himself, there are obvious rudimentary organs characteristic of the branchial respiration; and that therefore we must either

admit the type to be *double* in all animals, or that there were *two* distinct types held in view, viz. one pulmonary and one branchial; or that the original type was *aquatic*, and the pulmonary system became superadded as the human embryo ceased to be a fish, leaving him, however, with the rudimentary traces of his ichthyological existence: *une arrêt de développement* explained why the ichthyological organs had ceased to grow. But then, how comes it that the fish should have a rudimentary lung? Admitting that mammals are found during the embryonic condition to pass through the inferior forms of existence, the fish, the reptile, the bird, why should the embryonic fish be forced to pass through, but in an opposite direction, the higher forms of animal existence, which the rudiments of a *pulmonary* apparatus clearly indicate? The "*arrêt de développement*" doctrine will scarcely apply in either case. To cut short these difficulties and contradictions, I simply asserted that the original type in all the vertebrata was *double*, i. e. pulmonary and branchial, there being no other theory which seemed explanatory of all the appearances.

No one will readily believe that I was insensible to the importance of *proving* by *intuitive* inspection that the embryo of the vertebrata has both sets of organs, but the cares and anxieties necessarily attendant on the teaching a large and increasing class fully at the moment engaged my whole attention; specimens (human embryo), were difficult to be obtained, and their possessors unwilling to allow of their minute dissection: thus it was reserved for Rathke to discover the *branchial arches* in the embryo of the vertebrata having in the adult an aerial or pulmonary respiration; one of the greatest discoveries of modern times: thus proving, by intuitive inspection, the type of the respiratory organs to be, in most vertebrata at least, double, not single: and not neutral or common, but distinct from the earliest moment when the organs can be clearly made out.

The objections made by me to the doctrine of the transmutation of organs into each other were not limited to the respiratory organs: no one who had read Mr. Hunter's work on the Animal Economy could put any faith in the continental transcendental doctrines or

theory of the generative organs. When I was told that the generative organs in the embryo were at first all female or neuter, my answer was simply this—many animals are strictly hermaphrodite, that is, there are animals in whom *both sets of organs* co-exist. There must, then, be *two* types of these organs in nature, which is contrary to the simplicity of all her works, and contrary to the doctrine of the unity of organization. 2d. Most plants are hermaphrodite. 3d. Hermaphroditism, more or less complete, does occasionally appear, even in the highest of mammals. 4th. Rudimentary male organs exist in woman, and rudimentary female organs exist in man; therefore the type of the organs must be double in the embryo. Notwithstanding these *facts*, which Dr. Simson seems not to consider as such, the theory has been objected to on the same grounds as that regarding the respiratory organs, viz. that as yet the duplicity of the generative organs has not been *shewn* in the embryo. For my own part, I do not see that this is at all necessary for the confirmation of the theory proposed; but this, together with all the other objections made to the theory, I shall take the liberty of examining more fully at the conclusion of the memoir, which I have already stated was read to the Royal Society here in 1827 and 1828.

REMARKS
ON THE
RESPECTIVE VALUE OF THE
DIFFERENT TESTS

PROPOSED FOR
THE DETECTION OF A DIABETIC
STATE OF THE URINE.

By GOLDING BIRD, A.M. and M.D.

Assistant Physician to, and Lecturer on Materia Medica at, Guy's Hospital.

(For the London Medical Gazette.)

Is the treatment of a disease so intractable and fatal as diabetes too generally proves, it becomes of essential importance to detect the first deviation from health. The earliest evidence of this, in the disease in question, is, as is well known, to be sought for in an examination of the urine, as a saccharine condition of that secretion is at least the most constant, if not the necessary, accompaniment of

almost every phase of diabetes mellitus. It must not be supposed, however, that the existence of traces of sugar in the urine is indicative of the necessary presence of a confirmed diabetes; for it is beyond all doubt, that small quantities of this principle may occasionally exist as the result of a depraved state of the primary or secondary assimilative processes. Still, as far as experience has extended, it has shown that such a condition of the urine must be regarded with great anxiety as a most suspicious symptom; as one which, at least, points out the existence of a most deranged condition of the functions of the stomach, and one which may, in all probability, if its cause be unchecked, be the forerunner of one of the most intractable diseases falling under the province of the physician.

It is true that in advanced diabetes, where the disease has become confirmed, and the system has suffered severely from its depressing influence, the increased quantity of urine, coupled with its high specific gravity, and its general physical characters, will at once lead to the detection of the disease. Every one who has attended much to the pathology of the urine must have, however, met with cases of tolerably well-marked diabetes, *quoad* the general symptoms, in which, nevertheless, neither the quantity nor specific gravity of the urine would have, by themselves, been sufficient to lead to a suspicion of the true nature of the disease. A remarkable illustration of this fact occurred in the person of a young woman who, in the past summer, was a patient in Guy's Hospital (in Dorcas ward), under the care of Dr. Barlow. She had previously been a patient of my own, and then presented well-marked constitutional symptoms of diabetes, with the exception of the absence of the excessive thirst and diuresis. This girl was 28 years of age, but had never menstruated. The peculiar state of the tongue, which resembled a piece of raw flesh, and the harsh skin, induced me to examine the urine. The density of this fluid was but 1.022—scarcely above the average, and she passed but from three to four pints in twenty-four hours. I however found that it contained a large proportion of sugar. In a few weeks the quantity increased to eight or ten pints in twenty-four hours, and she ultimately fell a victim

to confirmed diabetes. There is at this moment a man, about 60 years of age, in the hospital (Naaman ward), labouring under diabetes, who, when he first came under my care among the out-patients, attracted my attention by his melancholic expression and harsh skin. On inquiry, I found that he passed but from three to four pints of urine in twenty-four hours, and the specific gravity did not exceed 1.024. It was, however, loaded with sugar. In this case the diuresis, or excessive discharge of urine and its high density, did not appear until some weeks after I had detected the presence of the disease. I have had, for nearly four years, a patient occasionally under my care (a green-grocer residing in Goswell Street), with diabetes, who, when first I saw him, had neither diuresis nor increased density of the urine; and these symptoms did not appear until some months after, although the urine was strongly saccharine the whole time. I need not multiply references to cases of this kind, as no doubt can exist as to the presence of diabetes, for at least some weeks, in cases where the indications afforded by the general symptoms appear to be negatived by what, on a very superficial view, may be taken for a healthy condition of the urinary secretion. Of course the question of the probable presence of sugar can at any time be solved by chemical analysis, but this involves a considerable expenditure of time, as well as an amount of tact in investigations of this kind not always at the command of every practitioner; and hence the importance of possessing some test of the presence of sugar easy in its application and satisfactory in its indications.

1. *Hünefeld's test**. — Place four ounces of the suspected urine in a glass exposed to the sun's rays, and add about six drops of a tolerably strong solution of chromic acid. In a few minutes, the mixture, previously orange-red, becomes brownish, and soon after assumes a bistre-brown colour, if sugar be present. These changes take place much more quickly if the mixture of urine and chromic acid be gently warmed before exposure to light.

This test depends, for its action,

* Journal für Practische Chemie, vii. 42. Copied into Berzelius's Jahresberichte für Physischen Wissenschaften, 1837, p. 385.

upon the deoxydizing power of the sugar, by which the chromic acid is reduced to oxide of chromium; for, after warming the mixture, the addition of a few drops of liquor potassæ produces a copious deposit of the green oxide. As pure chromic acid is prepared with great difficulty, I endeavoured to find some preparation which might replace it, and found that, by making bichromate of potass into a paste with sulphuric acid, and boiling the magma with not quite enough water to dissolve it, a solution was obtained which, when decanted from the crystals formed during cooling, contained enough free chromic acid, or rather of a combination of this with sulphuric acid, to exhibit all the changes with saccharine urine above described. In using this solution enough should be added to the suspected urine to give it a full orange colour, without which the subsequent changes will not be perceptible.

There is an important objection to this test, which renders all its indications liable to serious fallacy, depending upon the fact that all urine containing a normal proportion of colouring matter deoxydises chromic acid; and consequently urine, whether saccharine or not, will partially convert this acid into oxide. This change certainly does not occur so readily in non-saccharine urine as in a diabetic state of that fluid, but still is sufficiently marked to prevent Hünefeld's test being regarded in any other light than a fallacious one.

2. *Runge's test**.—Allow a thin layer of the suspected urine to evaporate on a white surface, as the bottom of a white plate, and, whilst warm, drop upon the surface a few drops of sulphuric acid previously diluted with six parts of water. With healthy urine, the part touched with the acid becomes merely of a pale orange colour, from the action of the latter upon the colouring matter of the urine; whilst, if sugar be present, the spot becomes deep-brown, and soon black, from the decomposition of sugar by the acid, and consequent evolution of carbon. This test is stated to be so delicate, that one part of sugar dissolved in one thousand of urine can be readily detected; and even when mixed with

two thousand parts, the indications are tolerably distinct.

Regarding the sources of fallacy to which this test is liable, I may mention the presence of albumen, which causes the acid to assume a tint nearly resembling that produced by sugar. There is also a peculiarity in its action which I have more than once had occasion to observe, namely, that if the urine is evaporated so as to be capable of being drawn into threads, it scarcely produces any change of colour, on the addition of the acid, until heat is applied. It is, however, a much more trustworthy test than the last, although certainly far inferior to the following.

3. *Trommer's test*.—This, which is the latest test suggested for the detection of sugar, was proposed by Trommer, of Berlin, and received the sanction of Professor Mitscherlich. An account of it is published in Dr. Simon's *Physiologische und Pathologische Anthropochemie**.

Add to the suspected urine contained in a large test tube, a few drops of a solution of sulphate of copper; a very inconsiderable troubling generally results, probably from the deposition of a little phosphate of copper. Sufficient liquor potassæ should then be added to render the whole strongly alkaline; a greyish-green precipitate of hydrated oxide of copper falls, which if sugar be present wholly or partly redissolves in an excess of the solution of potassa, forming a blue liquid, not very unlike the blue ammoniuret of copper†. On gently heating the mixture nearly to ebullition, the copper falls in the state of sub-oxide, forming a red and copious precipitate. If sugar is not present, the copper is deposited in the form of black oxide.

This test is founded on a fact long known, but not previously applied to the detection of sugar, of the power possessed by some organic matters of reducing oxide of copper as well as some other oxides to a lower state of oxidation. It certainly is the most delicate of all the chemical tests hitherto proposed for the detection of sugar in the urine, and will readily detect it in diabetic urine, even when very largely diluted.

* Berlin, 1842. Band 2, Seite 389. Attention has been directed to this test by Dr. Jones, in the last volume of the *Medico-Chirurgical Transactions*.

† Rose's *Analytical Chemistry*, by Griffin, p. 119.

* *oggenorff*, *Annalen*, Band 33, S. 431.

It is important in using this test that no more of the solution of sulphate of copper be used than is sufficient to afford a decided precipitate on the addition of the liquor potassæ. If this precaution be not attended to, a part only of the black oxide will be reduced to red sub-oxide, unless a very large quantity of sugar is present, and thus the indications afforded by this test be rendered indistinct.

In his remarks on this test, Simon observes, that the presence of the urea and ammoniacal constituents of the urine may in some cases interfere materially with its indications. To avoid this, he directs the suspected urine to be evaporated to a syrup, and digested in pure alcohol. The alcoholic solution being decanted, is agitated with dry carbonate of potass, and on being allowed to repose it separates into two layers, the upper consisting of the alcoholic and the lower of the alkaline fluid. A small quantity of a solution of sulphate of copper is then added, and the whole being warmed a yellow or yellowish-brown precipitate occurs in the lower layer, if sugar is present. I very much doubt whether this refinement of the test is ever necessary in practice, and it certainly has the objection of requiring a long time and a tedious manipulation for its completion, which is quite opposed to the character of a "test." As directed by Trommer, his test can be applied to urine in a few minutes, and its indications are most satisfactory.

4. *Test of fermentation.*—The development of the vinous fermentation on the addition of a little ferment or yeast to a fluid, has long been applied as a test for the detection of sugar. It was successfully employed by Professor Leopold Gmelin of Heidelberg* for the detection of sugar in the animal fluids after the injection of amylaceous food. Dr. Christison has, I believe, the merit of particularly suggesting the application of fermentation for the discovery of a diabetic state of the urine.

When a little yeast is added to healthy urine, and exposed to a temperature of about 80°, no other change occurs for some time except the development of a portion of carbonic acid mechanically entangled in the yeast. When sugar is present in the urine

thus treated it soon becomes troubled, a tolerably free disengagement of bubbles of carbonic acid takes place, and a frothy scum forms on the surface of the fluid, which evolves a vinous odour. These changes take place with great rapidity, even when the quantity of sugar present is very small. If the evolved carbonic acid is collected, the quantity of sugar in the urine may be determined by measuring it, as a cubic inch of the gas very nearly corresponds to a grain of sugar.

In certainly the great majority of specimens of diabetic urine it is not necessary to add yeast to excite fermentation, providing a sufficient temperature be employed. This, indeed, has been stated to be the exception, but from my own experience, I can assert that I have never yet left a glassful of diabetic urine upon a chimney-piece, when there is a fire in the grate, without having ample evidence of the development of fermentation within 24 hours. This test is certainly one of the best that can be employed, and is not subject to any obvious source of fallacy. It is, however, not so useful as Trommer's, as it cannot be appealed to at the moment, and requires time for the development of its indications.

5. *Test afforded by the growth of torula.*—It is a remarkable fact, that if the smallest proportion of sugar exists in urine exposed for a few hours to a temperature above 70°, and a drop of the fluid (taken from the surface) be examined under the microscope, numerous very minute ovoid particles will be discovered. In the course of a few hours more these become enlarged, and appear as distinct oval or egg-shaped vesicles, which soon become developed into a confervoid or fungoid vegetation, identical with that which appears in ordinary saccharine fluids when undergoing the vinous fermentation. In hot weather I have detected the oval spores of the *torula diabetis*, as the organic production is termed, in diabetic urine within a few hours after its being passed; and for the last two years I have constantly relied on their appearance as the indication of the presence of sugar in urine. I can scarcely conceive an error arising from mistaking other organic particles for these spores, as the latter are always oval or ovoid, whilst all other of the organic particles developed in the urine

* *Recherches Experimentales sur la Digestion.* Paris, 1826. Part i. p. 202.

are circular. As soon as the torula has appeared, vinous fermentation rapidly proceeds, and hence any possible inaccuracy arising from mistaking other particles for the spores becomes corrected.

The advantages of this test are the facility with which its indications are observed by the microscope with an object-glass of $\frac{1}{4}$ th or $\frac{1}{2}$ th inch focus, and the certainty of any possible fallacy being corrected by the subsequent development of fermentation. It is, however, less convenient than Trommer's, in consequence of the time required before its indications can be observed.

I have excluded from this list of tests that of Bouchardat*, depending upon the circular polarising power of the urine, as it is difficult in application, requires an expensive apparatus seldom at hand, and moreover has its indications seriously interfered with by the colour and imperfect transparency of the urine.

I have more than once had my attention directed to the probable presence of diabetes by observing on the patient's trousers white spots, arising from drops of urine having dried upon them. These spots consist of minute patches of dry sugar, and are readily removed by brushing. This, although it cannot be regarded as an actual indication of the presence of sugar, is, nevertheless, useful as a leading question in investigating the patient's history.

In conclusion, I would remark that, excluding Prof. Hünefeld's chromic test, as too liable to fallacy to be of any practical value, the other tests, arranged according to the accuracy and convenience of their indications may be thus placed—

1. Trommer's copper test.
2. Growth of torula.
3. Development of fermentation.
4. Runge's sulphuric test.

The profession must remain greatly indebted to Trommer for putting it in possession of a test for the presence of sugar in urine, so easy in its application, and so distinct in its indications, with the additional value of requiring but a few minutes for its employment.

Myddleton Square, Nov. 20, 1843.

CASES OF PULMONARY EMPHYSEMA AS A CAUSE OF DEATH.

To the Editor of the Medical Gazette.

SIR,

It was not originally my intention to have published the following cases, and they therefore are by no means so complete as I could wish, but lately reading some observations on pulmonary emphysema as a cause of death, and as one of them bears out a statement made, I have transmitted them to you, but without any remarks, lest I should intrude too much on your valuable space.—I am, sir,

Your obedient servant,

JOHN H. TRIPE.

Commercial Road, Nov. 20, 1843.

CASE I.—J. Pearson, æt. 29, wine-cooper, rather addicted to drink, short, but stoutly made, was first seen by me three years since, when he was of an earthy hue, and complained of cough and dyspnœa, which had troubled him more or less for some years, both being increased in winter, but especially the dyspnœa. About two years afterwards I again saw him: the dyspnœa had become constant, increased on exertion, or after meals; palpitation, cough, usually with but little expectoration; no wasting or œdema; there were also constant headache, and frequent giddiness; the countenance of a leaden tint; the lips large and purplish; lividity of the hands and nails; and fulness of the external jugulars, which did not disappear on pressing the upper part of the vein. There were local signs of emphysema, bronchitis, and dilatation, with hypertrophy of the right side of the heart. Roundness of the anterior part of the thorax; sound on percussion very loud, except at the lower part of the sternum, where the dulness was more marked than usual. Respiratory murmur scarcely audible; expiration longer than inspiration in the proportion of about three out of five; but the ribs and diaphragm were longer in performing inspiration than expiration; the rhonchi sibilans, gravid and mucous; the first sound of the heart varied on each side, on the left being normal, and on the right shorter, sharper, and clearer than natural; no bruit. After a short time he returned

* Described in my Lecture on Urinary Deposits, vide MED. GAZ. 1843, p. 683.

to his employment, and continued so with but little interruption until the middle of last month, when he called on me, at which time the dyspnœa was much aggravated, the lividity increased, the pulse quick, small, and oppressed. On the 28th, he was discovered by his friends insensible, as they called it, in bed. On my visit, I found him lying on his back, capable of being slightly roused; pupils contracted, but sensible; the pulse imperceptible at the wrist; the heart's action feeble, fluttering, and oppressed; respiration very difficult, but not stertorous. The face leaden; lips blue and very large; hand dusky, and nails livid. A dose of æther was administered. In an hour, the pulse having risen, he was bled, the pulse rising as the blood flowed; sensibility returned, and he spoke to those around, the countenance, lips, hands, and nails, becoming less livid. From this time he gradually relapsed, all the symptoms returning, and he died in 23 hours after the bleeding; stimulants having been administered by moistening his lips, for he resisted any attempt to introduce them into his mouth, even up to ten minutes before his death. A post-mortem examination refused in the most positive terms.

CASE II.—Miss Pearson (sister to the above), ætat. 21, of a leuco-phlegmatic habit, applied to me on the 3d of May last, and gave the following history. She had enjoyed good health up to a fortnight previously, never having had any acute disease, except about a year ago, when she was confined to her bed with fever, and acute pain of the left side. The present attack commenced with cough, dyspnœa, and feverishness, with expectoration of a yellowish sputa. On a local examination, there were bronchitic symptoms, the sound on percussion being unusually loud.

She was relieved, but not cured, by the treatment, and in July last again applied, complaining of constant dyspnœa, cough, palpitation, headache, &c.; the countenance being cadaverous, but not purplish; the lips rather red; the pulse small, soft, 100; the impulse of the heart weak, with local symptoms of emphysema, bronchitis, and slight dilatation of the right side, the latter not being well marked. From this time up to the end of September, when I ceased attending her, the dyspnœa increased, remaining per-

manent; agitation of mind, a full meal, or any attempt at exercise, increased it considerably, causing violent fits of palpitation and cough, terminating with copious expectoration of frothy and thick yellowish fluid. She remained in this condition until the 29th of October, when her brother's death being communicated to her rather suddenly, she became worse, and a most profuse discharge of blood took place per vaginam, without pain, which continuing, Mr. Dyte was sent for, by whom she was attended for three days previously to her death, which took place rather suddenly, and without a struggle, her mind being perfectly calm and collected. After some trouble, permission was granted to examine the chest, which was done by Mr. Dyte and self.

Old pleuritic adhesions of the upper lobe of the left lung; both lungs highly emphysematous throughout, the air-cells being much dilated, varying in size from a millet-seed to that of a large filbert, the largest being found on the surface immediately below the pleura; the cellular tissue was emphysematous, principally taking the course of the bronchial tubes. But little blood flowed on the section of the lung, and that fluid and black; the smaller bronchial tubes were filled with a yellowish puriform fluid, thick and tenacious, much resembling the contents of a tubercular cavity, without any albuminous shreds; a few crude tubercles were scattered through the left lung, but no cavities. The left side of the heart was thin and pale; its parietes flaccid, and not containing any blood; the right side was partially filled with black semi-coagulated blood; the cavity of both the auricle and ventricle larger than of the left, and about half the thickness or a little more; the blood contained in the large blood-vessels was black and fluid. An examination of the head was not allowed.

ON THE MICROSCOPE.

MEANS OF REMEDYING THE DEFECT OF ARTIFICIAL LIGHT.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following observations appear to you to fall within the scope

of your journal, I should feel obliged by your giving them an early insertion.

Your obedient servant,

J. W. GRIFFITH, M.D. F.L.S.

9, St. John's Square,
Nov. 13th, 1843.

Although matters relating to the microscope as an optical instrument do not, perhaps, belong properly to medical science, still, as the study of the microscope is now becoming, or has already become, a branch of medical study, any information tending to render its application more easy, and its use less injurious, will, I hope, prove neither unacceptable nor useless to the medical reader.

It must have been repeatedly noticed, by microscopic observers of any experience, that the only agreeable time for making minute observations is during day-light, and that examinations made at this time only can be relied on. The pure white day-light, furnished by reflection of the sun's rays from large floating cumuli, is that which best illuminates microscopic objects; whilst the orange or reddish-yellowish light of a lamp or candle wearies the eye incomparably more than the softness of day-light. There is also a marked glare with candle or lamp light: this is very annoying to most observers; so much so as to compel many to use the microscope by day-light alone, which few can have the opportunity of doing. To remedy this defect of artificial light, by showing the method of rendering it as white as daylight, is the object of the present communication.

The imperfections of lamp or candle-light appear to me to arise mainly from two causes: 1st, its being monochromatic; 2dly, the colour in excess being that which is most intensely luminous, viz. yellow. The first renders us totally unable to appreciate colour; the second causes a very unpleasant and injurious glare. It occurred to me that these might be overcome from the following considerations.

It is well known that, by the combination of a certain colour formed by the mixture of those existing in one portion of the spectrum, with that formed from the mixture of those remaining, that white light is produced. The two colours formed by these combinations, each consisting of that colour

which the other requires to compose white light, are called, for that reason, complimentary to each other. All we have to do, then, to render a reddish-yellow light white, is to mix with that colour the complimentary one. The colour must vary according to the nature of the light, and the quality of the combustible: if the light be reddish, a pale green glass, in addition to the blue, will be requisite. The readiest mode of ascertaining the proper tint is to fit the polariscope to the microscope; then to place in the stage some crystallized salts belonging to any other system than the cubic; next to arrange the analyzer and polarizer so that their planes of polarization are at right angles: by examining thus several crystalline specimens, a portion may be always found which is of exactly the same colour as that of the flame (which must be found out by comparison) by then turning round the analyzer, so that the planes of polarization become parallel, the complimentary blue tint will be found, and a piece of glass of this colour will be the requisite one.

In applying this principle to the illumination of microscopic objects, I found that, by passing the light, in its passage from the candle or lamp, through a piece of deep blue glass, I could render the light, as I had anticipated, perfectly colourless. By this light bodies can be examined by night with the same perfection and accuracy as in day-light, without that fatigue occasioned by the monochromatic light; moreover, colours are distinctly recognised.

The modes of applying this contrivance are numerous: a substance soluble in tallow, and supplying the requisite tint during combustion, may be added in the formation of candles; or another head may be added to the illuminator of opaque objects, and a plate of glass of the proper colour fixed in it, this being placed as near the light as possible, and between it and the mirror of the microscope. Again, a piece of the coloured glass may be fixed in the condenser ordinarily used for transparent objects; or the lamp-glass itself may be made of the requisite coloured material. The method of effecting this properly is to select the coloured glass by day-light, illu-

minating the microscope by a candle or lamp, and then placing the glass between the light and the mirror; the field will, if the glass be of a proper colour, appear of the same tint as the cloud light.

MEDICAL GAZETTE.

Friday, November 24, 1843.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medice* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

PROGRESSIVE CHANGES IN PRACTICE.

THE tendency of fact to become fiction, and the danger that long after the change has taken place it will continue to be believed and acted on as fact, is easily made evident; but the special embarrassments which such transformation causes are frequently felt to be unbearable, and therefore angrily shaken off with much of heat and impatience, from the true nature of the change not being perceived. The former scarcity of many drugs, the skill and capital required in their purchase, selection, and manipulation, and especially the scientific labours of the chemist, demanded an order of men possessed of a better education than that of most tradesmen, and raised the price of the materials in which they dealt. The information derived from studying and compounding prescriptions soon gave these men a practical knowledge of the medical uses of drugs—and made them practitioners. It was a fact in those days, or had been recently, that a certain skilfully compounded dose of medicine, duly bottled, corked, labelled, and otherwise technically treated, was worth eighteen pence, wholly independent of the skill required for its adaptation as a remedy to the particular case; for which a much larger sum had previously to be paid as the

fee of the medical attendant. It was evidently a fact worth knowing, when it *was* a fact, for patients paid the money cheerfully, so that large ledgers were filled, and large fortunes made, in the shops of apothecaries in former days. The College of Physicians did all the head work, wrote prescriptions, made pharmacopœias, and went about seeing, smelling, and tasting, that the compounds were properly made, and had not got musty, while the Sovereign in Council threatened with royal displeasure any departure from the authorised formulae, except by order of a learned physician. The apothecary likewise took the prescription from the house of the patient, and carried with it the directions which he received. He did not, however, long remain ignorant of the why and wherefore of his proceedings, but, as a naval commander, not content merely to carry sealed orders and ammunition, and to blaze away at the enemy, soon wants to know something of diplomacy, and puts other books on the shelves of his cabin than those on navigation, gunnery, and the articles of war, so the apothecary studied the theory and practice of medicine as well as the alembic, the herbal, and the pharmacopœia.

But he still continued to be paid merely for his drugs, though his skill in preparing them was become as nothing compared to the skill he had acquired in the practice of physic. Money was made hand over hand by the present fact, that he was almost always in attendance with the physician, and by the former fact, now become fiction, that each dose of medicine he gave (and many patients took six a day), was still worth eighteen pence. This was too good to last. The former fact had become a fiction; but it was convenient—it kept up the proper distinction between the apothecary and the physician; and, may we not add, was a tangible ma-

terial ground for the recovery of a disputed bill, such as would carry conviction to a jury, and enforce that remuneration as a right, for those professional services in sickness, which are so apt to be forgotten in health. The fiction, therefore, was kept up, that a dose of physic was worth eighteen pence, and the bills were presented and paid accordingly.

The public had got this fairly by heart; and now they began in various ways to be told another fact, namely, that the apothecary could write a prescription as well as compound the draught and superintend its operation. Still the disinterested attendant seemed to charge nothing for all this care and skill; the draught, which did the work, remained at eighteen pence. But a gratuity was often added to the bill; and if this was neglected one year, it was often suggested in the next by the word "attendance" put at the bottom, though without any charge; suggesting how much head work had been done for nothing, and how many physicians' fees had been saved.

By and by came distinct charges for visits, classically expressed in the ledgers by the word "iter;" and though these were often disputed, yet the majority of apothecaries becoming also surgeons, the claim was generally allowed, particularly in the country. But now the grocer, oilman, druggist, or whatever he may be called, seeing that *some* of these eighteen-penny draughts can be made for little more than the value of the bottle and the trouble of filling it—that he has got a steady hand, a clear head, a quick shopman, and a good character for intelligence with his customers, gets a Latin grammar and dictionary, and a young man to read prescriptions. He meekly suggests that he can afford to sell draughts for ninepence or a shilling, according to the

nature of their ingredients. Chemists and druggists, making an enormous profit on their materials, with small outlay in learning the art of using them, their trade becomes highly lucrative, and their numbers increase rapidly, each addition to their number taking somewhat from the gains of the apothecary as a compounder of medicine.

The draught, however, still being in theory (and that theory supported by nearly all the doctors' bills extant,) worth eighteen pence, and the competing chemists selling it for much less, the value of a prescription, no matter how obtained, becomes very great. With a prescription, argues the public, we may be cured for a few shillings, or even pence; without one we must have a doctor, and a doctor's bill. A general begging, borrowing, and stealing of prescriptions begins. What cured Mrs. A. of the bile will cure Mrs. B. To be sure, says the druggist. The dose is not strong enough, can't it be increased? To be sure, says the druggist, "or, here is a form *we* keep, that I think might suit you better;" and so on, till a long bill at the druggist's is substituted for a long bill at the doctor's, and a good deal more physic is got for the same money.

Not long ago it was the custom to set off the fiction that the apothecary's draught was worth eighteen pence, with an assertion that the druggist's draught was not; that he had no interest in the patient's recovery, and that his drugs were very inferior, and adulterated. But two wrongs do not make right, and this has long ceased to be a fact at any respectable druggist's, though it is said that adulteration was formerly carried on to a great extent even in the first houses.

It has taken a good many years to impress strongly on the public mind

this fictitious notion of the intrinsic value of physic; and it will take a good many more to erase it; but not until it shall have been erased will the skill and science of the general practitioner receive its proportional and just remuneration. It is in each man's power to add his influence in the right direction; it will require intelligence, firmness, integrity, self-denial it may be; but many influences are at work to promote this desirable end. The educated pharmaceutical chemist, getting a deservedly high price for his really scientific exertions in his own valuable department, renounces the pilfering gains of counter-practice (*vide* Pharmaceutical Journal *passim*); and well educated general practitioners, who can afford to wait awhile for the practice which they are competent to conduct, will, it is to be hoped, bear an increased proportion to the needy two-session-men, when once it is made clear that the profession is overstocked, and that immediate employment cannot be obtained.

The failure of the Society of Apothecaries to protect its members against the manifold aggressions from without has arisen from the extreme difficulty and embarrassment which attend the exercise of its penal attributes. Two distinct offices have been virtually confided to the Society of Apothecaries: the one is, the confining their diploma or license to properly qualified persons; the other is, the defence of their own licentiates from the unfair competition, and the public from the inefficiency, of the unlicensed.

In the first of these duties their conduct has been most praiseworthy, and their success remarkable; they have gradually improved the course of study recommended, and increased the amount of information required, till their licentiates are forced into the acquisition of a highly creditable

amount of professional knowledge. But as an engine of medical police, as the guardians of their own licentiates and the public health, they have signally failed, and the failures have been the inevitable consequence of a false position.

Practitioners of acknowledged competence have, in some instances, been attacked for practising creditably without their license; while ignorant persons have been allowed to secure a responsible and lucrative degree of medical practice under the pretext of selling drugs. This has raised some able practitioners, victims of their prosecutions, into martyrs, and many encroaching tradesmen, who have practised unscathed, into wealthy rivals. The more valuable effects of some recent trials in establishing the right of remuneration for attendance has come too late. Such right has long been tacitly conceded to the apothecary in all cases where the concession was worth having; those who are in good practice gradually dropping the custom of charging for items of drugs supplied. The poor, indeed, still pay for physic only; and this branch of the subject may be worth particular notice, and may furnish useful hints to the intelligent, industrious, and ill-paid general practitioner as to the best means of extrication from his present uncomfortable and undignified position.

We, for our parts, shall not be wanting in endeavouring to give a sound practical and profitable direction to prevailing discontents—from whatever quarter or whatever cause—persuaded that the candid admission of unpleasant truths is the best foundation for cautious reform.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

THE PRESIDENT IN THE CHAIR.

November 14, 1843.

An account of two cases of Rupture of the Ureter, or Pelvis of the Kidney, from external violence, followed by large effusion of urine into the abdomen. By EDWARD STANLEY, Esq. President, Surgeon to St. Bartholomew's Hospital.

THE first case was that of a boy aged nine years, whose pelvis had been squeezed between the wheel of a cart and the curbstone. Extensive suppuration ensued in the contused parts around the pelvis; and several ounces of matter were discharged by puncture near the left sacro-iliac symphysis. At the end of six weeks, an oblong swelling was observed in the right side of the abdomen, extending from the margin of the ribs downwards, to within a short distance of Poupart's ligament, reaching anteriorly to the linea alba, and posteriorly to the lumbar region. By pressure deep fluctuation could be recognised; but there was no pain. The urine passed naturally. A small puncture was made in the swelling, and a little clear yellow fluid escaped. Three weeks afterwards, as the swelling had become more tense and pointed, it was punctured midway between the last rib and the crista ilii, with a small trochar, when fifty-one ounces of a clear yellow fluid were discharged. After the lapse of eleven days, the swelling having again enlarged, fifty-eight ounces were removed in a similar manner; and sixteen days afterwards, sixty-four ounces were discharged. The swelling now increased very slowly, on which account it was not interfered with for nearly three months, when it was again punctured, and seventy-two ounces of fluid of the same character as before, were removed. On being punctured three weeks afterwards, for the sixth and last time, only six ounces of fluid were obtained. After each operation some pain in the abdomen was produced, which was relieved by leeches. To reduce the swelling, a large blister was at one time applied, and the ointment of iodide of potassium was used for a considerable time, but neither of these measures appeared to be of any service. The general health of the patient continued good. As the tumor ceased to enlarge, and did not perceptibly diminish in size, the boy was discharged from the hospital, nine months after the occurrence of the accident. He has been subsequently seen by the writer of this paper in good health, the abdominal swelling being still distinct, although smaller, and with less evident fluctuation.

The fluid which was drawn off was analysed at various times by Mr. Edward Ormerod and by Mr. Taylor; both of whom detected the presence of urea, and the other ordinary ingredients of urine.

The second case occurred in St Bartholomew's Hospital, under the care of Mr. Vincent. A woman was admitted immediately after having been knocked down by, and pushed some way before, the wheel of a cart. Her left femur was flattened, and she was besides much hurt, especially in the right hypochondrium, where pressure gave considerable pain. For several days she had much febrile disorder, accompanied by severe pain and distension in the abdomen, requiring venesection, the application of leeches, and calomel and antimony in frequently repeated doses. When the general distension and pain in the abdomen had subsided, there remained a circumscribed and painful swelling in the right hypochondrium, which it was thought must be connected with the liver. For some days the swelling increased, and fluctuation could at length be recognised; the patient, during this time, complaining of general chilliness, and having paroxysms of pain and throbbing in the swelling. It being supposed that abscess connected with the liver had taken place, a puncture was made in the swelling with a small trochar, when between two and three pints of a straw-coloured urinous smelling fluid were discharged. The urine had been throughout passed freely and in full quantity. In about ten days, the swelling having increased so as to occasion much distress, it was again punctured, and six pints of a fluid possessing the same characters as before were drawn off. In a few days the pain and swelling returned, and from this period the patient gradually sunk, and she died in the tenth week from the receipt of the injury. The fluid obtained from the abdomen was found to be albuminous, and to contain a small quantity of urea.

Upon examination of the body, a large cyst was found on the right side of the abdomen behind the peritoneum, extending upwards to the diaphragm, and downwards to the brim of the pelvis. A passage was found to extend from the upper part of this sac into the pelvis of the right kidney, the aperture being large and irregular, and such as might be expected to result from laceration of the membranous structure composing it. A preparation exhibiting the appearances in this case was on the table of the Society. The author concluded by adducing several arguments in support of his opinion, that either the ureter, or the pelvis of the kidney, had been ruptured in the first case, as was found by dissection to have happened in the second; and by adding practical remarks on

the effusion of urine into the cellular membrane.

Two Cases of Ulcer of the Stomach producing circumscribed Abscesses in the Peritoneum. By EDWARD J. SEYMOUR, M.D. F.R.S. Physician to St. George's Hospital.

The first of these cases occurred in a female servant, æt. 25, admitted into St. George's Hospital, Jan. 16, 1843. Two days previous to her admission, she had been attacked with sudden pain in the epigastrium and left hypochondrium, extending over the whole abdomen, accompanied by vomiting, which had, however, ceased. The countenance was sunken, and expressive of extreme distress; and there was pain over the whole abdomen, which was very tense and extremely tender. Notwithstanding the exhausted state of the patient, the presence of peritonitis, and the recent nature of the attack, indicated venesection. She was therefore bled to xxvj. , ordered calomel and opium (gr. iii. and j.) every four hours, and a turpentine injection. She afterwards had leeches and fomentations; and on the 18th expressed herself as "greatly relieved, and without any pain in the belly." On the 19th, she suddenly complained of most acute pain in the epigastrium and left side. Pulse quick and small, with excessive palpitation. The pills were again ordered, and a blister applied, and the pains were greatly relieved. The dejections were now healthy, and the abdomen throughout could bear pressure; but the pain continued in the left hypochondrium, and extended to the chest, with occasional syncope and impossibility of breathing with the left lung. Aphthæ soon appeared in the mouth: the pills were omitted, and light nourishment given, and for two days she appeared to be relieved. Without any increase of symptoms, however, she died almost instantaneously on the 27th, ten days after admission.

Post-mortem examination.—*Abdomen:* The left part of the transverse colon, and the anterior margin of the left lobe of the liver, were united to the anterior parietes of the abdomen, so as to form a closed sac, which was filled with foetid pus and some of the contents of the stomach. The left lobe of the liver was enlarged, and covered the greater part of the anterior surface of the stomach. On lifting up this portion, the contents of the stomach oozed out of a small aperture communicating with an ulcer situated about an inch below the middle part of the lesser curvature; its size was less than a shilling, and its shape oblong; the vascularity of the mucous membrane around it was but slightly increased. Another small ulcer was found at the lower part of the posterior wall, which had nearly

destroyed the mucous membrane. The convolutions of the small intestines were glued together by recently effused lymph. *Thorax:* The lower part of left lung united by lymph to diaphragm; lung healthy. Pericardium contained serum mixed with recent lymph.

The second case was also a female servant, aged 20, who had been ill for several months, was pale and emaciated, and complained of severe pain in the right hypochondrium and around the umbilicus. Pulse quick and weak; tongue red and glazed; had taken much purgative medicine without relief. About ten days after her admission she was attacked suddenly with violent palpitation of the heart; the pulse was quick and weak, and the skin cold; for the first time she coughed, and expectorated dirty purulent matter, very foetid. The matter being spit up freely, the patient's state improved, and she asked occasionally for food. On the 8th of December (a fortnight after admission), without any increase of symptoms, and after having taken breakfast, she suddenly expired.

Post-mortem examination.—The transverse colon, liver, and stomach, were glued together by old and firm adhesions, and in endeavouring to separate them, the parietes of the stomach gave way. On its posterior surface, towards the great curvature, was a large ulcer, which had destroyed all the coats, the deficiency being made up by the pancreas, adhering to the circumference of the ulcer. The remaining part of the mucous membrane of the stomach was somewhat thickened, but otherwise healthy. The upper surface of the right lobe of the liver was partially adherent to the diaphragm; the adhesions formed the walls of an abscess the size of a child's head, bounded above by the diaphragm, below by the liver, and on either side by the union of the diaphragmatic and hepatic layers of peritoneum. The matter in this cavity had ulcerated through the diaphragm, and made its way into the substance of the right lung, communicating with several of the larger bronchial tubes. There was a small quantity of serum in the right sac of the pleura. The right lung, with the exception of the adhesions to the diaphragm and the ulceration of the bronchial tubes, was quite healthy. In the left lung several patches of grey hepatization.

The author remarks that there are many cases on record of the perforating ulcer of the stomach. Those now related are remarkable, both from the length of time which elapsed between perforation of the stomach, and the death of the patient (almost every case on record, where the perforation was complete, having proved fatal within twenty-four hours of the attack), and also from the entire absence of vomiting after the first few hours. He alludes to the

prevalent opinion, that these cases, if not peculiar to, are far more frequent in females than in males; but an examination of the cases on record, he says, proves there is no foundation for such a conclusion, as they are nearly equally divided between the two sexes. In the ten recorded by Mons. Cruveilhier, nine occurred in men, and one only in a woman.

PROFESSIONAL ETIQUETTE.

To the Editor of the Medical Gazette.

SIR,

I TRUST that as the arbitrator of medical differences and the guardian of professional etiquette you will give an early insertion to the following statement in your valuable journal. Occasional editorial notices of such subjects promote a gentlemanly feeling, and maintain a wholesome discipline in the medical body. Your own opinion therefore of the case, with a few of your usually judicious comments on the principles that should regulate the conduct of practitioners in their professional intercourse, would much oblige, sir, your obedient servant,

A GENERAL PRACTITIONER.

Nov. 15, 1843.

A family removed in March last to my immediate neighbourhood from a locality six miles distant. They had there been attended for some years by a general practitioner. The lady, at the time of her removal, was within two months of her confinement. I was several times in attendance previous to this event; but as her old attendant was engaged before her change of residence, and had also attended her on a former and similar occasion, she wished him to do so on this. He accordingly did so. Three months afterwards I was again consulted for various maladies, and among them on account of a swelling in the breast, accompanied with pain, heat, and occasional redness. For this I prescribed purgative and alterative medicine, with leeches, cold lotion, &c. and enjoined attention to diet. Under this mode of treatment the symptoms of inflammation considerably abated, but the swelling still remained, and seemed to take a more definite form.

Well knowing the extreme difficulty of diagnosis in incipient affections of the breast, and the importance of giving early attention to them, I urged my patient to take the opinion of Sir Benjamin Brodie; at the same time saying I considered it impossible for any one (however great his tact or extended his experience,) to decide in its present stage. It might be a milk tumor, a chronic abscess, or a simple or some other tumor; possibly, though not probably, one of the malignant forms.

Things being in this state, the original medical attendant chanced to make a friendly call, and in the course of conversation the lady directed his attention to her breast. He examined it, and, *knowing* it was under my care, gave an opinion as to what the case was, when I had expressed myself unable to do so (that opinion being that it was a milk tumor), and left a prescription, directing it to be shewn to me. He was informed that the patient, at my suggestion, was about to consult Sir Benjamin, when he observed that she could not do better, and offered to accompany her himself; and upon her declining (for it was my expressed intention to go with her), he said that if *his* name was mentioned to Sir Benjamin, she would receive every attention, because he had originally been his pupil, and proposed that Sir Benjamin should write to him, on the ground that he would tell *him* what he would conceal from *her*; thus, as far as he could, taking the case out of my hands, thrusting himself forward, and most unceremoniously throwing me in the back-ground.

The patient has since consulted Sir Benjamin, who (if any one) has a right to dogmatize: he, however, with judicious caution, refused to give his opinion till he had again seen her at the expiration of a fortnight. He has just seen her the second time, and still feels unable to decide, though he leans to the opinion that it will prove to be an abscess.

I felt that the conduct of this practitioner was indelicate and uncourteous—not that which one gentleman should show to another—not that which might be expected from the member of an enlightened, liberal, and scientific profession; for I have ever found the man of science to be the man of humility, in accordance with the opinion of Lord Bacon, that “it is the nature of true knowledge to make man humble;” and where this humility exists, there will always be a respect for the opinions, and a considerate regard for the feelings, of others. Ignorance and presumption generally go hand in hand, whilst knowledge and humility are as inseparable companions.

Of the endowments and acquisitions of the party in question I am as ignorant as I am of his person, never having seen him; therefore these latter observations must be regarded as made in the abstract. It may, perhaps, be justice for me to state that he condescended to say my treatment was “perfectly right.”

I have for many years been in the habit of attending *with*, and for *very many* of, my brother practitioners; and I am happy to say I never experienced from any of them similar treatment.

DEATH OF MR. RUMSEY.

DIED on the 23d ultimo, at Gloucester, in his 78th year, Henry Rumsey, Esq. one of the oldest members of the College of Surgeons, and during fifty years an able and highly respected practitioner at Chesham in Buckinghamshire; where he succeeded his father, Henry Rumsey, who also practised for fifty years honourably and successfully in the same place, leaving at his decease two sons, the late Dr. Rumsey, of Amersham, who died in 1824, and the subject of this notice.

CLINICAL REMARKS

ON

STRICTURE OF THE URETHRA,
WITH ITS TREATMENT.

By B. PHILLIPS, F.R.S.

We have in this establishment a large number of old men, of whom many are constantly under treatment for disease of the urinary organs. Many suffer from stricture of the urethra; and to this division of the subject I now wish to direct your attention.

You must recollect, for it was under treatment not long ago, a case where, from the sensibility of the canal, I was obliged again and again to abandon the use of bougies for a time, even after we had succeeded in passing them through the stricture; in that case we at last smeared the membrane in the neighbourhood of the stricture with lunar caustic: you must recollect, also, how very remarkable was the effect—how perfectly well we were enabled to proceed with the bougie.

You may think that the foregoing, as well as the succeeding cases, were commonplace enough; so they are, but they are like such as you may expect to meet with in practice; and they are not always easy to treat, and it is for these reasons that I speak of them.

W. M. aged 45, had stricture of the urethra of long standing, which had given birth to several attacks of complete retention. On each occasion he had been relieved by introducing an instrument and keeping it in contact with the stricture until a strong desire to make water was felt; the instrument was then withdrawn, and a little water dribbled away after it. When I commenced the treatment of this case, a metallic flexible bougie was introduced several times, and kept firmly in contact with the stricture for an hour without penetrating into it. At last it passed on, and for more than an inch the passage felt rough. The dilating plan

was followed up, the instruments were left in the urethra for an hour each time, and at last the canal was restored nearly to its natural condition. In this case the tendency to contract anew was very slight—so slight that as much as six months have passed without the introduction of a bougie.

W. W. aged 41, had stricture of many years' standing, for which the treatment by dilatation had often been employed. His sole complaint was of the difficulty of making water, and the frequency of the desire. I attempted, but without success, on four occasions to pass bougies of the smallest size, both plaster and catgut. I then introduced, every second or third day, a No. 8: I kept it in contact with the stricture for an hour each time, and on the sixth trial it passed on. From this time the bougies were gradually enlarged; they were always kept in the urethra from half an hour to an hour, until the natural calibre of the canal was restored. At present he passes a bougie once a month, but he always finds that a sensible contraction has taken place in the interval.

The two men now present, and the one lately discharged, have exhibited no complication beyond a certain amount of irritability of the bladder, though in each the stricture was so close that nothing was passed through it for many days. You saw me try again and again to introduce bougies of the smallest size, and as often fail. You have also seen that we then resorted to the use of larger sized bougies, and that after failing several times, the instrument, by patience and perseverance, has passed on to the bladder. One of these men will be discharged to-morrow, but with the injunction to come here once a month, or oftener if necessary. In the third case we have passed two strictures, but we have not yet conquered the third.

You have lately seen under treatment other cases of what are called very close strictures of the urethra. They were none

of them so close but that water would dribble away; but they were all too close to admit the smallest sized bougie.

In those, as in most of the cases I have ever seen, the contraction succeeded to one or more attacks of gonorrhœa, and was, in fact, owing to an induration of the walls of the canal as a consequence of the inflammatory action set up at the part by a gonorrhœa. You will often hear of a kind of stricture which is believed to be independent of any such thickening; it is called *spasmodic*. If by a spasmodic stricture be meant an obstacle existing in the canal of the urethra to the passage of the urine, independent of any structural lesion, I believe it is of very rare occurrence, if, indeed, it can happen at all: but if we attach to it another signification—that it is a state of spasm determined by disease existing in the canal—then, undoubtedly, we may often meet with it. It is very rare that a permanent stricture, as it is termed, completely blocks up the canal, but as it prevents the bladder from completely emptying itself, the urine becomes more and more acrid, and when it comes into contact with the stricture it induces a certain amount of spasm, or at least increased contraction.

By a *permanent* stricture we mean a material obstacle to the passage of the urine on the one hand, and of a dilating instrument on the other, that obstacle being almost always constituted by a thickening of the walls of the urethra, the result of inflammatory action set up at the part. In most of the cases I have examined, the thickening has extended to a certain distance on either side of the point of greatest contraction, and has not much changed the character of the mucous tissue itself, but has principally affected the sub-mucous tissue; and this is a point which it is essential you should bear in mind for reasons which will appear hereafter.

You may find what are termed *bridle-strictures*, of which you can see a representation in Sir Charles Bell's work on the Urethra, but they are not often met with. How they are formed it is not very easy to determine. Goulard seemed to think they were constituted by a fold of mucous membrane. Morgagni regarded them as the results of small ulcers, and probably he was near the truth. Some pathologists have conceived them to be a kind of false membrane.

The older pathologists thought urethral obstructions were mostly caused by *excreescences*, *fungous growths*, or *polypi*. That such things have been met with in practice has been abundantly proved, but it is equally clear that the occurrence is extremely infrequent.

You may find the urethra blocked up at or near the orifice; when this happens, the affection is either congenital—a malformation—or it is caused by violence, or is the

result of ulceration. You may find the obstruction in the navicular fossa. It is then caused either by the retention of a calculus at the point, or by the consequences of gonorrhœal inflammation. You are aware that the external orifice is the narrowest part of the urethra; a particle of calculous matter may pass along the urethra until it gets near the meatus; it is too large to escape, and it is there retained, and may set up enough of irritation to produce thickening and contraction. The seat of inflammatory action during the acute period of a gonorrhœa is not far from the orifice; and a contraction may result from the inflammation so set up: but this does not happen frequently. Stricture is not commonly the result of acute, but of chronic, inflammation, which is not often found in that situation. You may find a stricture at any point between the navicular fossa and the curvature, and its occurrence is not rare; but it is at the curvature of the canal that strictures are commonly found. When we consider that this is the region where chronic inflammation is so commonly seated, that here the direction of the canal is so changed that harm may be done by the imprudent use of instruments, it is not surprising that it should be, *par excellence*, the seat of stricture.

Of the causes of stricture, out of all proportion the most frequent is gonorrhœa: probably out of every 100 cases of stricture which may come under observation 98 or 99 are owing to that cause. Many persons hold a different opinion, and say, if gonorrhœa be the common cause, how comes it that stricture is not most commonly found in the navicular fossa, which is, it is said, the seat of gonorrhœal inflammation? I have already stated that stricture is not commonly produced by acute inflammation; it is usually the result of a chronic long-continued action. Whatever may be the common situation of acute action in gonorrhœa—and it is by no means proved that it is the navicular fossa—certainly when chronic it is ordinarily found near the curvature. I have, however, known stricture to be produced by the injury done to the urethra by chordee. Some people think that strictures are more commonly the result of astrigent injections than of gonorrhœa. A gonorrhœa cured in a moderate time does not, it is true, often produce stricture; but when the acute symptoms gradually give place to a protracted chronic discharge, then contraction may be looked for as an impending evil. I do not mean that a slight discharge, though continued for months, or even years, is necessarily the precursor of stricture, but it is nevertheless true that commonly it is so. Now it is to cure those chronic discharges that injections are commonly used, and it is

rather a strong measure, under these circumstances, to refer the stricture to the injection rather than to the disease for which the injection has been used. In most cases the injection used gives no pain, and then no harm need be expected from it; but if it be painful, if it increase the inflammation at the diseased point, it may of course do harm. There is an opinion that the use of the bougie or the sound as a curative agent is a frequent cause of stricture. I hope this is incorrect, and think it is so. That many people fancy they have stricture when they have not, and that they proceed to consult a medical man on the subject, is true; that he examines the canal by passing an instrument along it, is also true; that if he be wanting in the necessary dexterity he may do harm, more particularly about the curvature, I cannot deny; that because there was some difficulty in passing the instrument he has used undue force, and done an injury which may lay the foundation of stricture, is of course possible. In point of fact, I have known patients who have had bougies introduced for months, sometimes with much pain, who previous to treatment made water by a full stream. But at last the number of men who go to be treated for stricture when the urethra is empty is comparatively small. I do not doubt, however, that strictures are often made worse by the mode in which they are treated. Strictures are sometimes produced by external violence. I have more than once known them to happen from confusion of the perineum upon the pommel of the saddle causing laceration of the canal. I have known them to follow the use of lithotomy instruments. They may happen, indeed, from any cause capable of setting up inflammatory action in the canal.

The ordinary signs of stricture are usually pretty well marked; for some time there has been a discharge, it may be so trifling in quantity as barely to mark the linen; it is slightly increased by any irregularity, still it is very little: it is usually the sequel of a gonorrhœa. There may be no other inconvenience complained of. The diminution of the stream is so gradual that it is not noticed; at last, the contraction, slowly as it grows, prevents the bladder from completely emptying itself, because the bladder, like every other muscular structure, is incapable of continued action beyond a certain time; that time is long enough to allow of the complete evacuation when things are in a natural state, but when the bladder is allowed to get too full the expulsive action is frequently not sufficiently sustained for the escape of all the contents. So when the canal of the urethra is made smaller than natural, a similar result follows. In this state of things a certain portion of the

contents of the bladder are constantly retained, and the desire to make water becomes in consequence more frequent. Instead of lying in bed from night till morning, he is disturbed once or oftener in the night, and then he goes to his medical man. Not, perhaps, because he thinks he has stricture, but because he has a little annoying discharge, and a frequent desire to make water. To the medical man the history of the case seems to point clearly to stricture; but he does not pronounce a positive opinion until he has passed a bougie along the urethra.

In many cases, however, we are not consulted until the stream becomes extremely small; or even until the urine dribbles away drop by drop, with a constantly recurring desire; with, perhaps, the parietes of the urethra behind the stricture giving way, to be followed by urinary abscess and fistula, or with some damage done to the prostate, the spermatic organs, the bladder, or the kidney. In this state complete retention is always impending; any slight irritation may cause the complete blocking up of a passage which before was barely pervious.

Now when you are called on to treat a case of stricture, the fact of the patient being able to pass even a very small quantity of urine, and that even with much straining, and the case where he cannot pass any, are capital points of difference. In the one case you have time before you, in the other every quarter of an hour may be doing much to seal the patient's doom.

Let us take the first case: the patient can pass a little water, though with much effort; your attention must be directed to make the passage larger, and for this purpose many agents have been recommended; but for practical purposes they may be reduced to two, *dilatation* and *cauterization*; for I will assume that under ordinary circumstances a prudent surgeon will not resort to any more violent means when the patient can still pass water a little at a time. Both those means have been regarded as permanently curative agents, the one acting, as has been supposed, by causing absorption of the morbid products by pressure, the other causing the destruction of the same product; the canal in either case remaining free. Once for all I tell you, that in cases of permanent stricture this is a result which you will not commonly witness, whether you employ the one agent or the other. You may make the patient's life comfortable; you may remove the danger which threatened him; but like suspected characters he must be ever after under "surveillance." I do not wish you to understand that this is the unvarying result, but still it is so common a one, that you must regard it as the rule.

Now let us see how these agents act; let us endeavour to estimate their relative value in

cases such as we are now treating of; and let us begin with *dilatation*. As a certain portion of water will dribble away, no violent means are necessary; neither is it imperative that the obstacle should be overcome at once. You must, therefore, be content to try mild means. The common plan is to pass a bougie to the part and insinuate it into the stricture, but as this is often not practicable, much unnecessary poking follows, and the evil may in this way be rather increased than lessened. You have been accustomed to see me pursue a different course, and I need hardly say, that I think it a better one. In two of the cases you have just seen, the strictures were so narrow that the smallest size elastic gum instrument did not penetrate into them; still you see that one of the patients can himself already pass a No. 10 bougie into the bladder, and I trust the other will be able to do so in a fortnight. In all these cases I use a moderate size instrument: I pass it down to the contracted point, and I direct the patient to keep it firmly in contact with the stricture for an hour, if he can bear it without much discomfort; if not, for a shorter time. In some cases, by the end of an hour, the instrument will pass on to the bladder; in others it has to be repeated three, four, five, or six times before the obstacle is passed: there are cases where even a longer time may be necessary, but usually, if properly done, half a dozen sittings will enable you to get through the majority of cases. When your instrument has passed through the stricture the remaining treatment is usually easy, but there are certain things to be borne in mind: do not be in too much haste, do not introduce the instrument too frequently, do not enlarge the canal too quickly. You may find the urethra become too sensible to allow of your going on, many days may pass before you can prudently use it again, and when you do you will find the parts resuming their former state.

Some persons regard the bougie as a *curative* agent in stricture, under ordinary circumstances. I do not think so. I always recommend a patient who has suffered from permanent stricture, and whose urethra has been made free by dilatation, to watch narrowly the size of the stream of water, and even though he may not observe that it is lessening, he will do well to pass a bougie himself, from time to time, to assure himself that the canal is kept free. The frequency with which it should be done must depend upon the case; one man will find it necessary to do it once a week or oftener; another will let one or more months pass without finding the introduction of a bougie necessary.

As to the treatment by dilatation, it is

certain that bougies may be used with less pain and danger than any other agent we can employ; they adapt themselves more easily to the curvatures, and excite less irritation, than metallic instruments, and the good is gradually achieved. The important question, at last, is this; do they merely act like a wedge, simply pushing the sides of the canal apart, and flattening any projections which may be found there? or do they cause the entire removal of the morbid product which constituted the stricture, so as to leave the parts in a natural state? I cannot doubt that, occasionally, a perfect cure is accomplished by the use of bougies; but it is difficult to say what was the exact condition of the parts in those particular cases. It is a notorious fact that, commonly, a permanent cure is not effected, and that the necessity for occasionally passing a bougie remains. I come, therefore, to the conclusion that the pressure of a bougie is, in a large proportion of cases, insufficient to procure the removal of the indurated matter causing the obstruction. Still, when dilatation is discreetly employed, the relapses are much less frequent than when it is imprudently employed. It is unwise to dilate too rapidly; whenever you do so, the return of the trouble is prompt also. You may, in the course of forty-eight hours, pass a No. 12 bougie into the urethra, which, two days before, would not admit a No. 2. This mode of proceeding is objectionable for two reasons: you are treating the urethra as an inert canal, you may induce in it very troublesome inflammation, and by the end of a week you may be prevented from proceeding further, and in another week the evil may be more serious than when the treatment was commenced: the indurated matter was not absorbed, but only put aside. The prudent plan I conceive to be what you see employed here. Do not irritate the part by poking against the stricture a small bougie, which at last will perhaps not penetrate, and may make matters worse. Introduce a moderate sized bougie, keep it firmly and equably supported against the obstruction, let it remain there as large a portion of an hour as it can be borne without inconvenience. If it will not pass on by that time, remove it; and if the urethra be in a quiet state, you may repeat the operation on the morrow, always letting the instrument remain in the canal as much as a quarter of an hour if there be no discomfort; if the patient complain of tenderness, you may let one, two, or more days pass before you subject your patient to a second attempt. In this way you proceed until the instrument passes on; you then gradually enlarge your instrument; and you must be guided as to the frequency of the introduction by the state of the canal. If the treatment can be

borne every day, there is no reason why it should not be followed up; if the sensibility be excited, you may do it every second or third day. When the canal is dilated sufficiently, you then lengthen the interval; at first you make it a week, then a fortnight, a month, or even longer; but ultimately the period of introducing the instrument must depend upon the tendency to contraction which may be manifested. You should, when the canal is free, teach a patient (unless you fear to trust him) to pass the bougie himself. If he be a private patient he will find it can be passed most easily before he gets up in the morning. So much I may say, that the relapses after the treatment of bougies are more manageable than those which follow canterisation or scarification.

Again and again *canterisation* has been proposed as the means of curing stricture of the urethra; still, at the present moment, it is little used in this country. This must be owing to one of the following circumstances: either the application of the remedy is difficult, the inconveniences attending upon its use are real and established, or the cure is not permanent. Many different caustic substances have been used, but at present it is upon the nitrate of silver and the caustic potash that most reliance is placed. Whatever caustic is used, the intention with which it is usually employed is to destroy the indurated matter which constitutes the obstacle.

Then, again, as to the mode of applying it: by some it has been sought to bring it in contact with the interior surface of the stricture; others have been content to apply it upon the anterior surface. We will now inquire, first, as to the practicability or prudence of *destroying* the morbid product; secondly, into the *mode* by which the caustic can be best employed; thirdly, whether, when used, *the cure is permanent*.

It is now a well ascertained fact, that the mucous surface itself is not much changed at the contracted point; that the indurated product is fairly and altogether outside of the mucous surface, very much limited to the submucous tissue, but continuous with the adherent portion of the mucous tissue. Now if that be, as I believe it to be, a well-established fact, it follows that, if destruction be carried out to the extent intended, there must be complete destruction of the entire thickness of the mucous membrane. In that case I apprehend a cicatrix would follow, which would occasion a contraction much more difficult to overcome than that to which it has succeeded. Although I by no means deny that the whole thickness of a mucous membrane may be destroyed by caustic, yet it is much less easily accomplished than may

at first sight seem possible. I have many times applied lunar caustic upon the mucous membrane of the vagina, but I have never destroyed the membrane by it so as to get a cicatrix. If you apply it again and again to the mucous membrane of the cheek, you will find you make very little progress; and I apprehend that, in the common run of cases in which caustic is applied to the urethra, the continuity of mucous membrane is not destroyed; the morbid product outside of it cannot therefore be destroyed. Eschars are no doubt formed and thrown off, but they make little impression upon the membrane of the urethra. It is unquestionably true that in twenty-four hours, or even much less, after the application of caustic, the patient may make water better than he did before the operation; but this is not because a part of the obstacle has been removed, for by that time the eschar is not come away, but because the morbid sensibility of the part is for the moment extinguished, and the urine passes over the point without exciting the parts to contract. I apprehend, therefore, that, in the majority of cases, the improvement which is often observed is owing much more to the extinction of irritability than to the destruction of the tissue. At the same time, a dilating instrument, a bougie on the one hand, a *porte-caustique* on the other, is kept steadily in contact with the part, and in the end the obstacle is passed.

For a long time caustic was applied to the anterior part of the stricture by means of the armed bougie: and when we know that it has been applied to a single stricture as many as two hundred times, we may readily admit how little destruction of tissue must follow each application. In all cases it is likely to act on the healthy tissue, and to cause accidents, among which tumefaction, threatening retention and hæmorrhage, were not the least frequent. The evils of this plan were long felt: at last it was proposed to avoid them by carrying the caustic fairly within the stricture, and applying it there, as it were from within outwards. From this method of applying the caustic much was expected; its action was to be confined to the morbid growth, and when the first eschar was thrown off, the opening was to be enlarged by so much. The objection to this plan is, that if you have to treat a close stricture, you cannot get your caustic into it; you must first enlarge the opening by bougies before you can use the caustic; and when so much has been done by bougies, it may be said why not go on with them?

Now let me say a few words on the relative advantages of dilatation and canterisation. There was a time when I felt a strong conviction that caustic was the most

certain curative agent in the treatment of stricture; a longer experience has satisfied me that that conviction was not well founded. I believe we know no means of effecting a permanent cure of advanced cases of stricture, but I think the best means we possess is the prudent employment of dilatation. You can always make the canal free by this means; and although it will commonly manifest a tendency to contract anew, yet the occasional introduction of a bougie may prevent this disposition from proceeding so far as to cause inconvenience. I do not doubt the cures that have been attributed to caustic; but in my opinion they have been mainly owing to the dilatation exercised by bougies and porte-caustiques employed in the treatment. I apprehend the good derived from the use of caustic is owing to the modification of the sensibility of the canal, which has allowed of a more unreserved use of dilating bodies than could have been had without it. It is possible that the irritation of the caustic may do something towards exciting the absorption of the morbid product, and that which the bougie could not do alone might be effected by such an association. Still it must be admitted that, whether each plan be used alone, or whether they be employed in combination, the tendency to contract anew is commonly observed, and is best arrested by the occasional use of the bougie.

Although the remedy is in the patient's own hands, when the diameter of the canal has been once restored—although the remedy can be applied with scarcely any inconvenience, and notwithstanding that you have pointed out to him all the evils that may result from neglect of the means that you put into his hands—it is astonishing how little you can trust to the patients using them. A patient who has suffered severely once, and who has been made comfortable by treatment, will most likely suffer severely again. He will tell you that he had not perceived any diminution in the size of the stream, and that therefore he did not think it worth while to pass the bougie; at last he gets alarmed, and finds he cannot pass it at all, makes many attempts to do so, perhaps irritates the canal, and may induce retention. This is the common history of such cases.

At our next meeting we will consider the more pressing and serious of the evils which are determined by stricture of the urethra.

ON CONSTITUTIONAL IRRITATION*, OR GENERAL DISTURBANCE.

By T. WILKINSON KING.

INTRODUCTORY CONSIDERATIONS.

Definition—A plan of the relation of the animal functions. Humoral agencies and their advocates. Varieties of assimilation—plan—The influence of the generative functions, of exercise, of the capillaries, and of the arteries.

CONSTITUTIONAL irritation is a general term for the phenomena of disturbance in the entire body, or for the cause which excites them. Disordered processes of health in countless variety comprise these phenomena. To unfold here and there one of these processes, to shew its connection with external causes, its influence on the other processes of the system, and its tendency towards restoration, or its end in destruction; these are our present objects. The ultimate aim by which we are actuated is no less than the hope of extending and clearing up the true basis of medicine; the rationale of health, disease, and remedies.

To obtain accurate information of the strength of the enemy, the point of his first attack, the course of his subsequent efforts to overrun and destroy, and to attack or defend with due regard to means and opportunities, are the essential objects of the general who combats diseases.

Having formerly defined, and partially illustrated, irritation as disturbance, whether nutrient, inflammatory, secretory, or nervous; and having endeavoured to explain a good variety of the forms of local irritation, and in some measure to illustrate the opinion, that the occasional differences in any one kind are in part regulated by the diathesis of the individual; and having observed that local disorders have a certain degree of influence over the states of other parts of the body not primarily affected, we naturally approach the study of those general or constitutional affections which constitute the most urgent examples of what is called irritation.

In an investigation of this nature it would be well were it possible to dis-

* Vide recent papers in this journal on "Irritation," "Cold," and "Heat."

tinguish very precisely between the local irritation and the general; and between that share of action which is more healthful and that which is most strictly morbid but for the present it must suffice if we can only shew that these distinctions actually exist, and are sometimes discoverable, and that the fact is essential in determining the treatment of all cases.

In a former account of general laws in medicine, we endeavoured to establish, as a fundamental principle, that health consists in a due balance of the functions of the body, and we offered the subjoined plan of the animal economy as a starting-point for subsequent studies.

Local disease may commence in any one function of the body.

We adverted at the same time* to the existence of heathful oscillations in most functions; to the importance of correlative acts and compensations, whether of increased activity as in plethora, or retarded operations as in periods of abstinence, or when one operation supplies the deficiency of another.

We spoke, too, of the natural order in which the functions become accelerated or decline—as from the influence of the mind, food, seasons, or exposure. We stated that disease is a disturbance of the natural balance in the form of local, combined, or general affections; that the course of the disturbance in any given case is strictly in proportion to the cause.

As a less general law we shewed that there is mostly in disease a tendency to spontaneous recovery, and that variability is a peculiar and sufficiently common character, and of great importance in practice.†

We have professed to regard it as an error to attend especially to any element of the body as the only fountain of disorder or source of remedial actions, but, as it will be admitted that some organs in particular must be more extensive and important in their actions than the rest, and as it is absolutely necessary to make separate studies of them, we shall not here seek to excuse a preference for the subject of the blood and the capillaries as before all others deserving of consideration.

The following seems to point, if not very correctly, at least with no little justice, to opinions which doubtless have never been obsolete since their ancient birth.

“Upon the whole, however, we cannot but regard the blood as in many respects the most important fluid of the animal machine: from it all the solids are derived and nourished, and all the other fluids are secreted; and it is hence the basis or common pabulum of every part. And as it is the source of general health, so it is also of general disease. In inflammation it takes a considerable share, and evinces a peculiar appearance. The miasms of fevers and exanthems are harmless to

* Vide First General Laws or Fundamental Doctrines of Medicine and Surgery, addressed to Students and Junior Practitioners, by T. W. King. London, 1840.

† See also, a Paper on Variable Disorders, Guy's Hospital Reports, 1840.

every other part of the system, and only become mischievous when they reach the blood: and emetic tartar, when introduced into the jugular vein, will vomit in one or two minutes, although it might require, perhaps, half an hour if thrown into the stomach, and in fact does not vomit till it has reached the circulation. And the like is true of opium, jalap, and most of the poisons, animal, mineral, and vegetable. If imperfectly elaborated, or with a disproportion of some of its constituent principles to the rest, the whole system partakes of the evil, and a dysthesis or morbid habit is the certain consequence: whence tabes, atrophy, scurvy, and various species of gangrene. And if it become once impregnated with a peculiar taint, it is wonderful to remark the tenacity with which it retains it, though often in a state of dormancy or inactivity, for years or even entire generations. For as every germ and fibre of every other part is formed and regenerated from the blood, there is no other part of the system that we can so well look to as the seat of such taints, or the predisposing cause of the disorders I am now alluding to; often corporeal, as gout, struma, phthisis; sometimes mental, as madness, and occasionally both, as cretinism.*

A great and summary argument for humoralism in physiology is the following:—

In the chest the heart is for the circulation of the blood, and the lungs for its purification. In the abdomen the digestive organs are for the formation and renovation of the same, and the great secreting organs are mainly for the depuration of the blood. In other systems we find nerves, bones, and muscles, freely devoted to the functions of digestion, respiration, and excretion. Now all this is designed to meet the waste, loss, and deterioration, which the daily and material support of all parts requires from the blood, which by nourishing or repairing all (through the medium of the capillary vessels) becomes deteriorated; fitted for excretion; and in want of additional assimulations. Are not all the organs here adverted to humoral in their uses? We see mechanical tubes only for humoral supplies! Is not almost every disturbance tantamount to some defect or

deterioration of the great compound "humor"—the blood?

The blood is liable to a great variety of alterations both in its quantity and quality, and upon these all the material molecular or capillary changes of the body are mainly dependent, whether of growth, nutrition, reparation, or morbid action.

It would be well for the student to supply himself with a complete analysis of the facts advanced by the investigators of the blood in health and disease. We shall produce but few of these, for without any disposition to distrust or disparage the statements in question, it may fairly be said that the truths are too few and isolated as bases of the general conclusions which we conceive may be justly asserted, if not amply defined. Without rejecting any truths, it is proposed to follow a more free and open course, which we feel confident the common facts from the bed-side and necroscopy will fully justify.

The uncertain and imperfect state of chemical and microscopic knowledge may be allowed as yet to form but comparatively feeble data, with respect to the vital agencies of the animal fluids, yet almost everything seems to depend ultimately on the advance of this knowledge. After Hunter, the labours of Babington, Magendie, Andral, and numerous others, offer essential truths to the physician.

The tables already quoted above indicate an opinion which in lecture we have occasionally dwelt upon at some length, under the terms maturative and perfective assimilations. One organ is said to possess arteries and veins, and of course it produces particular changes, according to its texture in the blood nourishing it. Various other organs have in addition efferent lymphatics. Another set have besides, vasa inferentia. We take the liberty to state *en passant*, that we admit no peculiar function of absorption or modelling with reference to the so-called absorbents, and that these tubes are chiefly specific in the nature of their contents and arrangements for a more rapid circulation than the veins.

The idea of perfective assimilation may be very simply illustrated as well as corroborated by reference to the numerous absorbent glands abounding in the bodies of mammalia. These

* Mason Good's Study of Medicine, 1822, Vol. 2, p. 34.

vascular appendages of the lymphatic system are surely destined only to alter or mature the fluids they transmit; whether it be the blood, the serum, or the chyle, and whether it be during health, or in the acts of ulceration, inflammation, or poison from without or from within. Chemistry or anatomy may farther unfold the present physiological statement, but it is already clear that with an active organization here are little bodies abounding and transmitting by numerous capillaries both lymph and blood for specific purposes, and that in no part of our bodies are the absorbents seen to reach the sanguineous current, but through these laboratories. If we presume a venous absorption in the stomach and bowels, may we not impute a correspondent elaborating action to the liver, and in one sense compare its two sets of veins to the inferent and efferent vessels of a conglobate gland? And when we arrange together the absorbed fluids of digestion, all those of the excretory glands, passages, and surfaces, those of the serous cavities, and of the solid parts, whose supplies seem only for their proper growth or nourishment; and lastly those of morbid or reparative processes; do we not perceive the necessity for admitting a general doctrine of dilutions and maturation—something which we may regard as a more complete working up of the animal materials, and which we may venture to call perfective assimilation?

Chemistry may one day help us to determine that the lymphatics of the excretory organs are so many sets of conduits for peculiar and important fluids of assimilation, and not merely for common aqueous fluid.

There is an observation connected with the termination of the thoracic duct which deserves a remark. It is, that the branches of the superior cava have manifestly a more ready circulation than those of the inferior, both on account of the influence of gravity and a more accurate arrangement of valves about the neck. Inspiration also modifies the thoracic currents. In relation to the lymphatic circulation in foetal life, the contents of the superior cava having a more or less strictly prescribed course through the right side of the heart, it will be perceived that the lymphatic products make their way

most directly to the placenta during uterine existence, as they do to the respiratory organs in after periods.*

We have before endeavoured to introduce the idea of perfective assimilation—see papers in the Guy's Hospital Reports, on the use of the thyroid body, and on the rapidity of the lymphatic currents. From the first paper the following is transcribed.

"All living organs receive supplies of the circulating fluids, calculated to maintain their growth or secreting functions; and, in particular cases, other additional ingredients form essential parts of the materials on which the organs are destined to operate. Now, we find that the circulating fluids, with or without these superadded ingredients, are submitted to the actions of various organs, and to as many different modes of operation, each for its peculiar results.

"These materials, these actions, and these results, may, for our present purpose, be arranged as follows. (See top of next page.)

"This comparative view of the influence of organs upon the fluids is very incomplete; but it may perhaps strike some as the diagram of an important physiological survey.

"The nervous system, which might form a distinct plan, has been excluded for the present, in order to simplify the view."

With respect to the thyroid gland, we must consider that its specific secretion passing off by the lymphatics is demonstrated. The vascular supply and muscular compressions of this gland deserve notice.

The supra renal bodies may appear less admissible as organs of assimilation. The size of each body in the fœtus, the very abundant distribution of arteries over its surface, the radiated structure of its external or cortical layer, and the large and beautifully ramified veins throughout its internal vascular layer, all conspire to indicate that a supra renal gland has an active and important destiny to fill. Its constancy†, both in infancy and after life, seem to attest that it is an essential organ. The little vascularity which is found in its outer substance so uniformly is only analogous to the appear-

* Mr. E. Cock made this reflection to me at the time of the publication of Sir. A. Cooper's work on the thymus gland.

† Amidst abundant opportunities, we have been looking at these glands for years, and have never missed them in man, or in the animals which

Colon	Blood <i>arterial</i> and fæces . .	Blood <i>venous</i> , colic fluids, &c. (<i>in lymphatics</i> , and perhaps veins), and excretions.
Lungs	Blood <i>venous</i> of all kinds, chyle, lymph, and pure air	Blood <i>arterial</i> , lymph, mephitic air, and water.

ance of paler parts, whose activity we are well assured of, as a periodical circumstance, which it may be important to remember: indeed, the comparative difficulty of injecting its numerous superficial arteries is very analogous to what we experience in the salivary glands, and other parts subject to periods of repose.

The alternations of excitement and relaxation, which are common to all

parts in different degrees, are, in certain cases, most complete, particularly after birth, or when the fulness and wide intervals of our meals, &c. demand and insure the marked periodicity of innumerable functions.

The proportionate size of the part in question is, doubtless, greater in the fetus than in the adult, although it is, we think, quite certain that the organ increases after birth, and remains beyond the middle period of life much larger than it is commonly found in infancy; and also that its subsequent decline is in no respect more marked than that of any other gland.

When we speak of the spleen as having a function analogous to that of the preceding organs, and entitling it to be classed with them, we would by no means exclude the idea even of a more important office being performed

possess them. It has, we believe, recently been attempted to prove that the venous blood of the supra renal bodies is peculiar even in the adult. We confess, however, to having sometimes regarded the body as a mere atrophied organ, especially in later life. Its persistence, without any use, might be attributed to venous distension within from its peculiar location. After dissection we found the two supra renal bodies weighed in a fetus near term, dr. j.—sc. ij.; boy, æt. 3 months, sc. jss.; girl, 7 years, dr. ij.; female, 24 years, dr. ij.; male, 43 years, dr. ij.; do. 55 years, dr. ij.—sc. ij.; old female, dr. ijss.; oldish man, dr. ij.

by it; but allowing a fair share of importance to its numerous lymphatics, and their necessary activity, may reasonably require us to admit, in some degree, either an improving or deteriorating influence as one action of the organ. The simple fact, that the veins of the spleen join those of the porta, affords us good ground for concluding that its blood is important to the function of the liver. The proper structure of the spleen, as it is developed in man and different animals, is reticular and elastic, though in various and regular gradations, as I think our museums at Guy's can in part testify; and it will, perhaps, now be scarcely disputed by any one, that varying states of distension are proper to the organ.

We need scarcely say that this function of perfective assimilation has been too little, or erroneously, regarded, if it should only appear to be proved that we know as much of the organs in question as of the ordinary secreting glands, excepting perhaps some detached points of their chemical history. It will still remain to be regretted that so little is understood of all. If any one were inquired of as to the design of the spleen, the absorbent glands, the thymus, the thyroid, or of the supra renal bodies, does it not appear that the most certain and general, and important answer, should relate to the changes which each of these parts produces upon the fluids circulated through their tissues, regarding equally the sanguineous and absorbent vessels?*

With a varied organization, and more than abundant nutritive supplies, and with large and numerous absorbent vessels, we cannot doubt that humoral changes, and of an eliminative character, are essential objects. Many may, indeed, hesitate to regard these as the first, or very important, ends proposed; but it must be admitted that they are marked and constant effects of the structures under consideration. For our own part, it seems difficult to suppose the main office of all these parts is not one of a maturing as well as eliminative kind; in fact, a *function of perfective assimilation*.

The fluids of the vesiculæ seminales, &c., as they seem capable of being absorbed, present curious matter for consideration; indeed, it may be that the evolution of these secretions, and their subsequent transmission into the circulation, are as necessary to the vigour of many organs as the excessive loss of them is prejudicial to strength. Common experience seems to indicate this. May it not also be, that many modifications of syphilis, as well as of marasmus, should be more particularly regarded in this light than they have hitherto been? It requires also to be remembered, that as warmth, a sore, or the normal uterine functions, may be conducive to the free developments of health, so the due performance of the male function may facilitate healthy actions. The idea of nervous exhaustion may be admitted (should it not be sudden?) but it is not to be supposed that this idea explains all the debility which tardily follows excess. Leucorrhœa is humoral loss and deterioration, and not merely nervous irritation.

Much has been thought of the influence of the cerebellum on the generative functions, but in them, for our part, we see chiefly humoral circumstances in operation. Languor and wasting (animal triste) follow excesses. Gradually the material supplies are allowed to accumulate, and vigour and desire are renewed. Ejaculation seems only equal to defæcation or parturition. The evolution and secretion of the generative organs seem essential to mature the materials and form of the rest of the body.

With wasting diseases, the genital organs become quiescent, or permanently decline. With full nutrition they grow active, and excite the mind as if the blood knew not where to get out: and this is a figure of more than theoretical importance. With moderate diet, and determination of mind and effort to other functions, the reproductive may remain tranquil.

In the case of one individual, fair and little pilous, at the period of convalescence following suppurating tonsils, we have very many times noticed the beard stronger and darker for four or five days; but this phenomenon has failed to take place if the recovery was interrupted, and we never found the event occur under any other circumstance. The numerous periodic and

* The oscillation, or varying activity, of these changes, as well as the opinion of a reservoir principle, requires attention; but this would be more appropriate in the examination of particular functions. See the account of the thyroid gland, before referred to.

successive changes in animals relative to generation cannot but be in a great measure humoral. To restrict the cerebellum to a confined periodic action does not seem justified by facts, and sexual imperfections have not been found to involve defects in the cerebellum of animals, notwithstanding the assertions of Gall. In fine, a common analysis of the animal processes requires that humoral, nervous, and physical causes be taken into the account at every turn. Doubtless some courage depends on judgment, but does not much depend on vigour, repletion, skill, and sense, or instinct of ability? With a firm circulation the face can hardly blush or blanch; without it, the knees may tremble, though the mind is clear, if not calm. These are not less humoral than nervous changes. Fear paralyses the muscles, the veins lack support, and the heart blood. The valour of a drunkard, a fowl, or a lion, are periodic, and not merely cerebral. The last, with repletion, and no safety-valve, is the greatest coward and cripple of the three.

It may be excusable to remark, that a little mass of corroborative illustrations to our present view is to be met with in several of our former papers. We are well assured, also, that pointed remarks of a like tendency are to be found scattered amongst other works. Perhaps even if the reflections of those who observe were as freely known as the views of compilers and self-constituted critics, the occasion is passed for advocating humoralism except in the way of defining and extending it. It might engage a considerable chapter to review the several effects of exercise. Muscle, joint, bone, secretory organ, nervous and circulatory functions, consume and deteriorate blood, and so react on each other. After eight hours' march with a gun, one throws himself down to rest for an hour, and rises refreshed. Excretions, absorptions, and reparations, have been busy. Without fresh food, or with only the concluding digestion of a preceding meal, balance is restored between the vessels of exhausted parts and the reserves of nourishment, as in the vertebrae and various tissues. The surface is quiescent, the muscles brace the vessels; these with the heart adapt themselves to the reduced mass of blood, and capillary activity is confined to the most weak-

ened parts, as of necessity. Thus repair destroys the necessity of repair. It is said, "the smaller arteries have a distributive power according to the wants of a part, and that circulation is active according to the changes which the blood effects on the part." (Brit. and For. Quart. Rev. 1839). We think this incorrect. Capillaries and all living tissues have an assimilating power which bears some proportion to their wants, but their nutrition, like secretion and inflammation, depends much on the blood supplied to them. "Inflammation," says the same reviewer, "is often only a disturbed state of parts tending to resolution," but this is like darkness, which tends to light. If not pure reparation, there is disease, and this is not arrested till the blood is changed. The revolutions humoral are like the hours of the day.

Exercise is to be very cautiously enjoined in opposition to the sense of lassitude. If the nutrient materials of muscle are deficient in the system, little effort can be endured with safety, and little is required to induce all the nutritive deposit that the body can spare to the muscles. Exercise becomes exertion, and the feeble muscles, made more feeble, too soon consume their poor supplies. This view applies to all tissues individually and separately, and is involved in the explanation of every disorganization.

From what has been said already, as from what follows, there is reason to conclude that for the most part, in vital actions, the blood and the capillary being necessary to each other, and to the containing tissues, they must be regarded as one organ. And as all the changes which result depend, for the most part, on the state of the blood, whether for health, or disease, or reparation, we do not scruple to speak of the functions in question under the name of humoral.

Poisons, remedies, or victuals, having entered the blood, it is in the capillaries that their ordinary effects are to be sought for, and whatever their extraordinary effects may be we shall not now inquire. As the properties of different parts of the body are peculiar, so must their nutrition be of distinct kinds; and in the same way we should expect to find the several tissues variously affected by the capillary permeation of particular matters.

It is not easy to speak too strongly of the importance of the capillary system. One great starting-point of the humoral pathology is doubtless this—that the capillaries are essentially dependent on the blood for their health, as well as even for their primitive existence, and all their occasional redevelopments. Thus we are again impressed with the necessity of weighing the peculiarities of the blood. As to the connexion of the capillary functions with nervous influence, it is a matter which we do not intend to dispute, but still would rather regard it as most intelligible when other topics have been fairly appreciated.

We deem it necessary to observe, that innumerable, active, and universal as the capillaries are, they may be found every where in a nearly equal state at the same time; and that not only must there be a certain correspondence of activity between the whole and the heart, but also some kind of balance must be maintained between the capillaries of different parts; as, for instance, between those of the surface and of the interior, or those of the lungs and bowels, or of the skin and kidneys. Here we perceive sometimes commensurate actions, and sometimes compensatory ones. Again, we may see, as it were, three parties concerned in reference to the natural balance of actions, for whilst cold obstructs the functions of the skin, and the heart itself is in consequence temporarily impeded, the circulation in the deeper organs becomes augmented, and ultimately the heart reacting on the impediment, its force adds further to the deeper actions, supposing the superficial to remain obstructed. Still this is but a simple case of physiological correlation, in comparison of the complicated relations which render innumerable parts more or less dependent on each other for an easy or natural share of the influence of the circulation. We must conclude, that the capillaries (as well as is their blood) are in a great measure maintained in health, or driven to disease, by the humoral results of digestion and absorption, maturative and perfective assimilations, and of excretion. Heat and cold have their agency; light and electricity may have theirs. Mental disturbance, and physical violence, are other sources of disturbance which still in part affect the blood humorally.

The place for the appropriate consideration of intimate material changes in the substance of any organ, may be determined to be amongst the capillary changes, or, in other words, amongst the instances of disturbance in the capillary balance; and this whether the changes relate to nutrition, inflammation, reparation of injury, or specific affections. May we not safely speak of the capillaries, with their blood, as the most important, if not the sole, agents in these processes?

One or two reflections on arteries generally may not be deemed out of place.

When an artery transmits blood with unwonted facility, as when the part it supplies is suddenly active, or growing, or inflamed, we may presume the first effect in the vessel to be contraction; for the vis a tergo remaining the same, the facility of the ulterior circulation is greater and the distension less. Now, the contraction of an artery will diminish its own nourishment and render it feeble, and then it must dilate. Its nourishment now, again, is increased, and it is ready to resume its pristine calibre. But if the above be just, there will be a succession of dilatations, &c., until there is an equal balance between the general arterial distension, the action of the artery in question, and the capillary action which it has been preserved to maintain—suppose the growth of a tumor, or of a stag's horn.

Let us also remember, the artery of an *inflamed* part has not a healthy nutrition. Let us next suppose the local action arrested, or even declining, the activity of the capillaries is failing, and the arteries cannot so readily empty themselves: their distension is still not greater than that of the whole arterial system. Where shall we look for the cause of their decline or contraction? Their nourishment has been sufficient only, but we shall find local actions set up elsewhere. Arteries contract with hæmorrhage, and subsequently dilate through defect of nourishment. The larger arteries of the gravid uterus, as of many inflamed parts, may still be weak through scanty or defective nutrition. The febrile state is defective nutrition, and most evidently what is called *asthenic inflammation*. We hold all inflammation (not reparation) to be defective nutrition.

“One of the most interesting facts established by the hæmodynamometer is

the uniform amount of pressure exerted by the blood upon the coats of the arteries in every part of the body; those in the immediate vicinity of the heart being distended by an equal force with those the most remote from it. M. Poiseuille made the experiment on the carotid, and on the muscular branch of the thigh of a horse, and notwithstanding the very great dissimilarity in the diameter and distance from the heart of the two tubes, the displacement of the mercury was exactly the same in both.* Arteries are made thick by the column distending them, and become thin, as on the head, where they have little to resist within.

This equality of pressure throughout the entire arterial system† is, observes Magendie, an extremely important fact, in a practical point of view. It shows that if the practitioner desire to lessen the quantity of fluid in circulation, it is of little consequence what vessel he opens; for the equilibrium of pressure is simultaneously re-established in all the vascular tubes.—(Lect. 6.)

M. Magendie considers the heart the efficient organ of capillary impulsion. In a paper on the "Safety-Valve Function of the Heart," we have shown by the venous sphygmometer, as well as by a variety of facts and arguments, that in the main the arterial impulse suffices to propel the blood beyond the capillary system.—(Guy's Hosp. Rep. p. 837.)

It will be our next object to show that the foregoing considerations are essential to the study of inflammation and fever, and even of struma and cancer.

36, Bedford Square.

ON THE
EDUCATION OF ARMY SURGEONS,
IN A LETTER TO

SIR JAMES McGRIGOR, Bart.

Director General of the Medical Department
of the Army.

— — —
SIR,

SIR GEORGE BALLINGALL has lately addressed a letter to the Right Hon. Sir Robert Peel on the subject of the education of the medical officers of the

public service, in which he recommends that a chair of military surgery should be established in London and Dublin, such as now exists in the University of Edinburgh.

The worthy knight's zeal for the benefit of that department of the public service over which you have so long and so honourably presided, has led him to conclude that the endowment of these chairs is to remove a difficulty, under which it is well known that the medical department of the army at present suffers. But, with all deference to the excellent authority of so able a professor, I must be permitted to state, that if what is called "military medicine" is to be taught as a separate branch any where in Great Britain, it can no where be so well learned as in that school which you founded, and which your exertions have raised to a degree of eminence, which renders it the most suitable place where military surgery can be taught in this country.

The museum of the medical department of the army at Fort Pitt, Chatham, contains morbid specimens of diseases, numerous and many, taken from the bodies of those who have fallen victims "to the diseases to which soldiers are liable," and collected from every corner of the British empire. And many of these preparations of morbid anatomy are further illustrated by drawings, casts, and paintings, while all are accompanied by every particular of the disease of which the patients died. What other school can be wanted? Where else are we to find such means for teaching?

But the school wants a teacher! And this is the more surprising, since there are so many in the army who could fill the appointment with so much honour to themselves, and so much benefit to the service, and that, too, without drawing an additional penny from the already overburdened finances of the country.

Chatham, constituted as it is at present, with its General Hospital for the invalids of the army, its large garrison of troops, and its museum and library, is the only place where a young man can be properly initiated into the nature of the duties of a military surgeon. Whatever we see makes a deeper and more lasting impression on our minds than what we hear; and a course of lectures unaided by those practical resources, which Chatham possesses,

* Vide an account of Magendie's Lectures on the Blood, in Dr. Hay's American Journal of Medical Science, November, 1839.

† It is not to be forgotten that gravity gives different degrees of pressure to various parts of the circulating columnal mass.

must be, at the best, but of doubtful benefit. "Anatomy and chemistry," said the illustrious Sir Charles Bell, "require demonstration. They are, therefore, the most essential sciences to be taught by lecture, in all colleges of medical instruction. The practice of medicine and surgery requires to be taught by the bed-side of the patient. But without saying that elementary courses on medicine and surgery are useless, *yet they are those which may be supplied by diligent reading.*"

That the want of a lecturer on morbid anatomy and operative surgery at the General Hospital, Fort Pitt, is much felt, I can well bear testimony to, for it was my fortune, during the time I was stationed there, to become acquainted with the sentiments of a great many of the department on this subject, and I never knew any other opinion to prevail. He should likewise be curator of the museum, and, in addition to this, his duties should consist in pointing out, in the form of lectures, the beauties of the museum, and in both demonstrating the various operations of surgery on the dead body, and in seeing the young men perform them. By this plan, the assistant-surgeons, before proceeding to join their regiments, would be made thoroughly acquainted with what the museum contained, and they would be, therefore, better enabled to add to its greatness; they could scarcely fail to become excellent anatomists, pathologists, and operative surgeons; and having arrived thus far, they would only then require practice to make them accomplished medical officers.

The young men, by being called upon to perform on the dead body the different operations in surgery, in the presence of others, and under the guidance of one appointed for such a duty, would readily attain to a proper knowledge of a department of the profession always important among the qualifications of an army surgeon; and they would be enabled to proceed to their respective posts with a degree of confidence in themselves, which, it may be safely alleged, is not common for them, under existing circumstances, to do.

The museum of morbid anatomy has now arrived at that degree of excellence and magnitude, that it can no longer, with the prospect of much good, be under the immediate care of one not pro-

perly qualified for the task. For it may be said with much truth, that it will take an accomplished anatomist a good many months before he knows well what it contains, and it will occupy a much longer portion of his time, before he can either prove of any particular service to it, or to those who have to seek for information from it.

Candidates for appointments to the medical department of the army should be required to proceed to Chatham, before being examined at the Army Medical Board, as is the present custom; when, after undergoing a sufficient course of instruction there—its duration depending altogether on their previous acquirements—they should be publicly examined, *i. e.*, they should be examined in the presence of the other candidates, by the principal medical officer and the staff surgeons. If the candidate acquits himself creditably at this trial, he might then be ordered to appear before the Medical Board for final approval.

This examination at Chatham ought to be purely practical, and regularly searching. Either in the wards of the General Hospital, or in those of the Provisional Battalion Hospital, the candidate ought to be made to examine into the case of any patient pointed out, and at once, and in the presence of the examiners, be required to name the disease under which he suffered, to mention its peculiarities, and to state how he distinguished it from other diseases; and subsequently, aside from the patient, he ought to be required to give the general history of the disease, its various terminations, and what was likely to be its course in the case in question. The candidate ought likewise to be called upon to perform the different operations in surgery on the dead body, in the presence of the examining medical officers; and, at the same time, he ought to be required to describe the readiest and best method of performing a post-mortem examination. And lastly, he ought to be required to point out in the museum specimens of the different disorganizations of structure likely to be produced, provided a fatal termination was the result, by the different diseases he had been called upon to describe.

This examination being conducted in the presence of the other candidates has much to recommend it, and little

against it. All will be benefitted by such a course of proceeding, and the candidate, if found wanting, will be in a position which he will find to be approved of even by his companions. The odium of rejection will be entirely on his own shoulders; his spirit must be roused to better deeds, if he has any; and on being again put at the bottom of the list of candidates, or merely remanded for a certain time, whichever may be judged most right, he will be unable to solace himself with the delusive idea that he has been unfairly dealt with, or that he has been put back in order to make way for one of greater interest. I say he will be unable to do this, because I take it for granted that there will always be that discrimination among his fellow candidates, that spirit of fair play and sincerity of purpose, which, together with their knowledge of the very subjects on which he foundered, will lead them to approve of the conduct of his judges, and, with manly dignity, to assert their sense of the propriety of the sentence. If, on the contrary, he be approved of, he has then reason to rejoice that he was thus publicly tried. He cannot but feel proud to look his fellow candidates in the face, and, with becoming modesty, to extort from them, whether willing or not, his just claim to their congratulations and respect.

A public examination, thus conducted, has likewise its good effects upon the examiners; it compels them to enlarge their field of examination, and to increase their store of knowledge; and it obliges them to act with all honesty and uprightness of purpose.

By the present regulations of the Army Medical Board, candidates for appointments in the service are not only required to possess the diploma of either the Royal College of Surgeons of London, Edinburgh, or Dublin, but they are likewise called upon to produce certificates of having attended several courses of instruction not included in the list of qualifications demanded by these bodies for the granting of their license. Candidates for the medical department of the Army are often, in consequence, at great additional expense and inconvenience, necessitated to again repair to some medical school for the purpose of obtaining these extra certificates, and they are subsequently required to pass a

certain probationary period at Chatham before being commissioned.

It is firmly believed by the writer of this letter, that if gentlemen possessing the diploma of either of the Colleges specified, were, in consequence of it alone, to be considered eligible for appointments in the service, and were only required, in addition, to undergo the course of instruction and examination herein mentioned, they would be saved both much time and expense, and the character of the army medical officer, as a surgeon, in every respect bettered. I assert this much, because, no where in Britain, can the candidate be better able to render himself excellent in pathological anatomy and operative surgery than at Chatham; and all, who are acquainted with what constitutes superiority in our profession, will at once allow that, these being taught in the practical manner which the establishment at Fort Pitt admits of, few courses could be better calculated to render them eminently useful in their profession.

Besides, were such a course of instruction once instituted, the benefit to candidates entering the service would not be the only good derived. Officers, who had been for a long time abroad, on again arriving in this country, would hail with much satisfaction the ability to renew their knowledge in an establishment of their own, and with the assistance of one whose chief interest it would be to attend to theirs. Therefore, the more effectually to carry this plan into execution, and the better to render it worth one's trouble and acceptance, a well-qualified young man would require to be promoted for the purpose. He might be gazetted, Assistant-Surgeon Thomas Pitt, from the 100th Regiment of Foot, to be a Staff-Surgeon of the second class, and Lecturer to the General Hospital at Chatham*.

Manifold would be the advantages which would accrue both to the department and the service, by the appoint-

* I do not mean that, although promoted for this purpose, he is not to do the usual duty of a staff-surgeon. On the contrary, the teaching and looking after the museum should be in addition to his other duties. In civil life, surgeons both lecture and toil from morn to night; and army surgeons are as fit, and just as willing, to do the same, provided only that they are encouraged. Early promotion would be good encouragement, and the duty required would not be great.

ment of such an officer: for, after a few years' creditable service in such a situation, he ought to be considered as possessing strong claims for further preferment. The talents which recommended him for this, his first step in the ladder of promotion, ought, during his career as a teacher, to be so much improved by the peculiar advantages of his station, that he could scarcely fail to prove an ornament to the department to which he belonged, and to reflect a lustre on its members generally. Moreover, the prospect of being thought eligible for such an important post, would always have its due influence with many: it would encourage them to keep up their knowledge, and to look forward with a lively hope to such an honourable stepping-stone to further advancement. Officers of a high order of merit and acquirements would thus be ensured to the department: in course of time they would multiply, and spread themselves abroad among the different divisions of the army; and they would do a credit to our profession, and confer benefits on our fellow-creatures, not easily to be described.

I have thus advocated the appointment of a youngish man to the more slavish duty of the museum and anatomical rooms, for the double purpose of affording encouragement to the assistant-surgeons, and, in progress of time, of disseminating in the army generally a very superior style of surgeon—one, whose future elevated position would be won rather by the cockade *in* his head, than by the number of years he had worn one *upon* it. But although I have done this much, I am, nevertheless, of opinion, that the principal medical officer at Fort Pitt should likewise be able to teach, and be required to give, periodically, a lengthened course of instruction on the medical history of armies, on camps and on campaigns, and on all those peculiar duties which occasionally fall to the lot of the army surgeon. Length of service, and the practical knowledge thereby attained, ought to qualify him well for the performance of such a duty.

Two such courses of instruction combined, as those I have pointed out, ought to be more valuable to the younger medical officers of the army than a mere course of lectures on military surgery. And that some such additional course of instruction is re-

quired, may be admitted from this fact, that young surgeons, in consequence of the number of studies to which they have to apply themselves in order to obtain their diplomas, are too often found, just after passing the College, to have received a "mouthful" of much that is good, but not a "bellyful" of that which is most useful; therefore, in order to make them superior as surgeons, this "bellyful" of the really useful ought to be afforded them; and as this can be well and most effectually done by the adoption of some such plan as this I have proposed, it ought not to be withheld. However, young surgeons must themselves work, and on no account forget those beautiful lines of Horace,—

"Qui caput optatam cursu contingere metam,
Multa tulit fecitque puer."

"The youth, who hopes the Olympic prize to gain,
All arts must try, and every toil sustain."

FRANCIS.

I have the honour to be, sir,

Your most obedient servant,

FRANCIS CALDER,
Assistant-Surgeon 2d Life Guards.

SPASM OF THE GLOTTIS.

To the Editor of the Medical Gazette

SIR,

DURING a visit which I lately made to Brighton, I was called by a family residing in Brunswick Terrace, to the following case, and as it presents a peculiar modification of a prevailing epidemic with hysteria, perhaps the details may not prove uninteresting to your readers.

One night, about eleven o'clock, as Mr. G—, the master of the family, was retiring to rest, he heard, on passing the room of one of the female servants, a peculiar sound, resembling the sonorous clangor of croup. On visiting the patient, almost immediately afterwards, I found her in great distress, breathing laboriously, and the spasmodic action in the throat was so urgent as almost to threaten immediate suffocation. She threw herself wildly about the bed, complained of pain in the head, and her eyes were suffused and injected by the impeded respiration.

It appeared that the paroxysm had seized her during sleep, and had continued some time before she was

awakened by a sensation of choking. The pulse was rather full and bounding, which might, I think, be ascribed to her alarm, and the efforts she made to draw her breath; and her bowels had been for some days somewhat constipated. She was placed under repeated doses of the compound ipecacuanha powder with calomel, and a draught with æther, camphor, and other antispasmodics, which afforded speedy relief; and in a few days she so far recovered as to be able to attend to her duties as upper nurses.

What may be termed *idiopathic* spasm of the glottis, in adults, is a disorder of rare occurrence, but several cases are recorded of fatal spasm resulting from irritating causes in the neighbourhood of the larynx: these arose from impacted food, and acute laryngitis, producing spasmodic action of the glottis, not inflammation, for no inflammatory action could be traced as having extended to the part.

From the previous history of this girl, I learnt that she was of a highly *mobile* temperament, easily wrought upon by accidental circumstances of the moment, and that she had suffered from frequent attacks of hysteria, and, in fact, attacks of the same nature as the present one, though of less violent a description. Had I not known this, and had the disorder been more tardy in its accession, I might probably not have hesitated, in so urgent a paroxysm, to pursue a different and more decided line of treatment. The event, however, justified the diagnosis, as the attack gradually yielded without depletory measures.

The exciting cause was ascribed by the patient to exposure upon the beach to a bleak north-easterly wind, which, in the latter days of October, prevailed at Brighton.—I am, sir,

Your obedient servant,

R. H. ALLNATT, M.D.

Parliament Street, Whitehall,
Nov. 18, 1843.

DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

I ENCLOSE you the following case of delirium tremens, with some remarks on the disease, as to its nature and cause. Should you think them worthy

of your notice, perhaps you will insert them in your valuable periodical.

I am, sir,

Your obedient servant,
WILLIAM F. SOLTAN, B.M.
© Coll. Hall. Oxon.

21, George Street, Plymouth,
Nov. 7, 1843.

William H——, æt. 29, cellarman to a wine-merchant. General health reported to be good, with the exception that at times he has suffered from what his wife terms "bilious vomiting." Is said to be of *very temperate habits* (?) On Monday morning, Sept. 4, he awoke his wife at 2 A.M. telling her that "he felt very odd, but that he did not know what was the matter with him." He got up, however, as usual, at six, and went about his work, which he was soon obliged to relinquish, as an attack of diarrhoea came on, which at that time was very prevalent in this town. For this he put himself under medical treatment, and it was soon checked. On the Monday evening, however, whilst his medical attendant was visiting him, he was seized with a fit of an apoplectic nature, on recovering from which he was much confused, and was not at all conscious as to what had occurred. From the peculiarity of manner which he then evinced, it was conceived that these might be the premonitory symptoms of an attack of delirium tremens. It was not, however, until the following day that the case became so marked in its general character as no longer to admit of a doubt as to its nature. From the Monday, on which he was first taken, to the hour of his death, he had no sleep. In defiance of all the ordinary remedies, the symptoms were only aggravated, and on Thursday, at 10 P.M., I was sent for to see him in consultation, and found him in the following state.

There was great anxiety of countenance; the eyes were incessant in their movements, but there was not the slightest intolerance of light; the head was natural in its temperature; the tongue was moist, somewhat blanched and flabby; the pulse was 130, weak, small, and compressible; the skin was bathed in perspiration, over the whole surface of the body; there was nothing peculiar in its smell; the perspiration of the left side was cold and clammy, as were also the extremities; urine had been freely passed during the day;

the bowels had been open once. The patient at this time was out of bed, having partly dressed himself, and was very desirous of going to his work. There was a general tremor of the whole muscular system. The quickness with which he answered every word which he heard spoken, though not addressed to him, was quite characteristic. He at times imagined that he was occupied in lifting casks, and he would call upon his fellow servants by name, to be more energetic in their labours. In this way he continued for an hour, and it was with some difficulty he could be persuaded to remain in bed. During all this time he knew me, and those that were about him. He now fancied that customers were inquiring into the qualities of particular wines, and in his answers a thousand incoherent ideas were crossing his mind, disjointed and unconnected.

Throughout the whole progress of the disorder there was no attempt at violence, nor was any irritability displayed, with the exception of his resistance to any restraint which was imposed upon him. At half past 11, the poor fellow became more laborious in his efforts. He imagined, though in bed, he had to lift some heavy weight, and his muscular efforts at this moment were most remarkable. They resembled more the spasm of an epileptic or convulsive fit. But with all this, the mind in its delirious state still kept pace. He continued in this condition for about two minutes, and then, with a faltering voice, and faint cheer of fancied success, he fell back exhausted on the pillow. From this moment he remained quiet, with the exception that he sang a verse from the Canadian boat-song. The sweat was as profuse as ever, and the tremor excessive. At length subsultus tendinum came on, the pulse became weaker, and at one o'clock, A.M. just three hours after I first saw him, he breathed his last. During the whole of this time he pertinaciously refused all the remedies that were ordered for him, constantly declaring that he had had enough.

Such is the brief history of a case deeply interesting in every point of view. Here is a man, who every person believed to be *remarkably sober, because he was never known to be drunk,*

and yet he is attacked with delirium tremens of the worst kind. On occasions such as these one is always ready and willing, if we can, to lean on the side of mercy and charity; but when it does so happen that every symptom is so well marked, and every characteristic of the disease so fully developed as to admit of but one conclusion, it then becomes our duty, however painful it may be, no longer to conceal the real nature of the disease.

Of all diseases to which mankind is subject, there perhaps is not to be found one more extraordinary in the nature and development of its symptoms, than delirium tremens. Who can read the phenomena detailed in the history of the case above given, and not reflect on the great mystery which hangs over this disorder? What, I would ask, are the most prominent features of delirium tremens? Great excitability, with depressed vitality. In the case before us the pulse was weak and flagging, and yet the muscular system did not seem to sympathize in the depressed power of the heart's action. Again, here is a man who, an hour before his death, is apparently full of energy and strength; but like the flame which blazes for the minute, then suddenly falling and flickering for a few moments, expires, he is a corpse before us, ere we can realize the danger of his position. Why, then, have we death here, or what is it that so rapidly extinguishes life? Surely these are questions which it would be well for us if we could satisfactorily answer. Will examination after death solve the difficulty? Let the morbid anatomist and pathologist reply in the affirmative, if he can. In all *post-mortems* that I have ever seen of persons who have thus died, no morbid appearances have corresponded with the nature of the symptoms during life. But what is the condition of the blood in this disease, and what change has taken place in its elements? When symptoms become so general as those which herein occur, we must look for some general cause as giving rise to their phenomena, and what so probable as an altered quality of the blood? It will be allowed by all, that the poison are accelerated or retarded, severe or mild, according to the or unhealthy condition of the blood, or, in other words, accordi

vitality; and hence it is by blood-letting they are rendered more quick in their operation, and more marked in their effects, as by this process the vitality is lowered.

Delirium tremens is a disease of the whole system. Every nerve, every muscle, and every other texture of which the body is composed, is alike affected by its cause. It is a species of general convulsion, not confined to, or dependent on, a peculiar set of nerves or muscles. I believe that in this disease the poison of alcohol is exerting its influence on the economy; and that its cause does not depend, as is usually supposed, on the sudden withdrawal of the accustomed stimuli, so much as upon a peculiar condition of the system, which calls the hitherto latent powers of the accumulated poison into operation. To explain myself somewhat more fully, I will take the case of a man who is an habitual drinker, without being an habitual drunkard. If he be a secret tippler, he may continue his propensities, and never suffer from the slightest symptom of this disease perhaps for years. Why, then, has he been exempt? The vital powers of his system have been able to resist the noxious qualities of the poison. But let that vitality from any cause be lowered, and then see what will follow. All the effects of the accumulated drug will forthwith be developed in the symptoms of delirium tremens. Alcohol is doubtless in the system of the habitual dram-drinker; it is in his very blood, and more or less is carried by that blood into every organ through which it circulates. It is not, then, the mere subtraction of the stimuli that gives rise to this disease, for many are the instances which may be adduced, where the habitual dram-drinker, influenced by religious or other motives, has suddenly given up his wonted habits, and has gone directly from one extreme to the other. In such cases there has been no ednecating or tutoring the system for its new condition, and yet no evil consequences have resulted. Now, if this opinion as to the cause of delirium tremens be correct, namely, that it depends more upon a lowered vitality of the system than upon the withdrawal of the accustomed stimuli, I think it might somewhat affect the ordinary method of treatment which is adopted

in this disorder, for if such be the case, it is the presence and not the absence of the alcohol which is telling upon the body; a distinction of no little importance. We may often recognize in the habitual drinker one or more symptoms analogous to those of the disease, though he continue for year after year, and never have any decided attack. Look, for example, at his trembling hands and his quivering voice, both of which are doubtless dependent on the same cause, and may be termed *tremor potantium sine delirio*; and though it does occasionally happen that the most notorious drunkard is exempt from them, yet whenever they are witnessed in those who are in health we may pretty accurately infer their cause. With these few remarks I shall for the present leave this interesting subject, with the intention of resuming its consideration at some future period.

ON
IRRIGATION AND WATER-
DRESSING
IN THE TREATMENT OF STUMPS AFTER
AMPUTATION.

To the Editor of the Medical Gazette.

SIR,
HAVING read in the MEDICAL GAZETTE of September 1st, a letter by Mr. Leach, on irrigation and water-dressing in the treatment of stumps after amputation, I beg to refer to my cases published in the GAZETTE of June, 1842. In the second and third the treatment was water dressing, and were quickly healed; the first case was plastered and tedious, but the disease, fungus hæmatodes, which caused the amputation, was formidable. I am happy to state that the man enjoys good health. I wish to add another case in testimony of the utility of water-dressing in flap-amputation, and as I was doubtful of its applicability in the circular operation, I shall avail myself of Mr. Leach's experience when an opportunity offers.

George Robert, æt. 23, met with an accident in his left wrist about two years since on board-ship at the Newfoundland fishery; he thought it was only a sprain, and continued his work. When he applied to me, four or five months

ago, the back of his hand was distended with matter, and he suffered acute pain. I gave exit to the matter, and fixed the starch-splint to favour ankylosis; I also prescribed iodine and sarsaparilla.

He attended for a few weeks, and was apparently improving; however, he discontinued coming, and as he lived six miles from me, I lost sight of him till the 31st of August, when he sent for me to visit him. I found he had removed the splint, and was applying cold water by the advice of an amateur physician; he had cough, was emaciated, had not slept for many nights from the pain of his wrist; he told me two of his brothers died of decline. He was anxious for the amputation, and as I could not discover, on examination, any organic affection in the chest, I had him brought into town, and on the 3d of September removed the fore-arm at the middle third with double flap, as described in Liston's Operative Surgery: four ligatures were applied, the flaps kept in position by one central suture; no plaster was used, but lint wet in water fresh from the pump, which was continued for seven hours; half a yard of oiled silk protected the bed, and conducted the water into a vessel. In former cases, where attendants were scarce, I applied the cold water by means of woollen threads suspended from a saucer over the stump.

The isinglass plaster and warm water-dressing with oiled silk, were then applied and changed often. On the second day the suture was removed; on the third the flaps were supported by a bandage; he had slept well, and suffered very little pain: on that day he walked from his close lodging to breathe the sea air: his cough was improving. The seventh day he went to his home in the country, and came every morning in a cart for me to dress his stump. On the ninth day the last ligature was removed; the stump was very healthy, and closed: it was cicatrized within a month from the amputation. The granulations were touched two or three times with lunar caustic. When last I saw him he could press on the cicatrix, and was about to have an apparatus fitted to the stump: I directed him not to work too soon: he still coughed a little.

I consider the cold water acts beneficially in causing the vessels to con-

tract, and in preventing much effusion and swelling: warm moisture is subsequently requisite, to encourage suppuration, till the ligatures are removed, when it becomes a simple wound, and heals by simple means.—I am, sir,

Your obedient servant,

ALEXANDER LEIGH, A.B. M.B.

(For the *London Medical Gazette*.)

Hermaphroditism: a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

PART II.

It can scarcely have escaped the notice of even superficial observers, that there are many organs and parts of animals of whose use or functions we are altogether or nearly ignorant. The inquiring mind is stimulated to attempt the discovery of the uses of the various parts of animal bodies by a principle inherent and imperious; the same which urges us to assign a cause for every thing, as "all things come by cause." If the mind be cautious, it suspends its judgment as to what is obscure and doubtful; if metaphysical, it flies to abstract and mystical causes; if ignorant and prejudiced, it resorts to sophistry, subterfuge, and falshood, to support the flimsy theories daily devised by minds of this description. No good reason can be shown why anatomical and physiological science should be exempt from the general fate of other sciences, and consequently we meet with all these applications, or misapplications, of human reason to diverse and invert *uses*, for the complicated machinery of animal bodies. The obvious uses of many parts were not to be mistaken, and it might even be shewn of others why they do assume this or that form; but it will be found that the extent of correct reasoning in these matters is excessively limited—to a degree, indeed, that few persons ima-

gine, and still fewer are willing to believe.

That parts exist in animal bodies of all kinds, with whose uses we are not acquainted, is, then, an undoubted fact; it might even be almost shown that they have no use, without qualifying it with the phrase essential. Parts of the kind I speak of exist in the human body in its adult and fœtal state, in the male and female of man and of most other animals. Organs which we know to be essential to the existence of one class of animals, exist in others where evidently they cannot serve any useful purpose; for it is not with animal bodies as with machinery, however complicated, in the investigation of which the mind is fully aided by a knowledge of the *intentions of the artist*. His wisdom is unfolded to us, but who can guess at the plans of nature in all her details? To meet these difficulties, anatomists, physiologists, and others, have devised a number of principles, with a view to explain the presence of these organs: thus, the horse has but one toe on each foot which is perfect, but two small rudimentary toes are known to exist on each side the perfect one; and these are called rudimentary, supernumerary, useless as a part of the foot, but placed there by a *general analogy* of structure which nature is said to observe in the construction of animal bodies; and thus we frequently find physiologists employing phrases similar to these: "the parts we now speak of are present in this animal, not because they are required, or are of any use, in the æconomy of the individual, but because nature loves analogy, and has placed these superfluous organs there to preserve an analogy in her works."

I have always thought this style of reasoning, or at least the language employed to express its results, exceedingly faulty, and even absolutely incorrect, but have not, until the present time, seen what could advantageously be substituted for it. All animals are formed upon one plan; for abstractedly and physiologically considered, there is but one great object in their creation, in the exercise of the functions constituting life. Aristotle, Galen, and most anatomists of those ages, contented themselves with stating these analogies in a general way, descending only to

minute and particular details occasionally, and with a reference to certain organs, such as those of secretion. These doctrines of analogy were well understood by them, and formed a good basis for their physiological reasoning.

Anatomical science has been progressive; and thus attempts have been made to give to these somewhat vague and ill-defined doctrines of the ancients a more precise character. It could not be overlooked, that the human being, during its fœtal state of existence, passes through forms which do not permanently belong to it; that these forms are generally fugacious, and intended to be so; but that occasionally they are permanent, and thus establish a strange, mysterious, and unexpected resemblance, between man and animals placed lower in the scale of being; and hence the doctrine of analogy came to be pushed still further, and it was laid down as a law, that the human fœtus, and indeed the fœtus of all the mammalia, is *forced* to pass, in its embryo and fœtal state, through various grades or types of organization, proceeding as it were from below upwards; from the most simple to the most complex; from the zoophyte or polype to man.

If any of the mammalia happen to present at birth anomalous and irregular structures, they are speedily traced to some regular structure in the lower divisions of the scale of being; the absence of the limbs at birth in an animal naturally possessing them, is simply a repetition of the structure in certain reptiles; and, besides, it was obvious that in the very early condition of the embryo the limbs are not formed. If the head were wanting, it is no prodigy; are not the acephalous mollusca without heads? if the intestinal tube terminate in a *cul de sac*, this is the exact state of certain echinodermata; and that an animal high in the scale, and in whom the sexes are naturally divided into two individuals, requiring both to constitute a species, should yet in some rare cases possess both kinds of organs, here anatomists, supporters of the doctrines of "formations arrêtées," saw nothing extraordinary in all this, for many of the lower classes are hermaphrodite; and as the embryo of the higher, man not excepted, has to pass, is forced to pass, through all the various shades of organization, the circumstance of his

being formed occasionally with hermaprodite structure could not be regarded as extraordinary or unexpected.

That these doctrines are in a great measure abstract and metaphysical, no reasonable person, I think, can doubt, though it is very probable that they may be, and indeed already have been, adopted as great physical truths, capable of demonstration by intuitive or direct observation of structure, by persons who, the less they know of anatomical and zoological matters, are more anxious to catch at metaphysical speculations as to the structure; like the young physicians described by Galen, who were fond of discussing *general doctrines* about the *membranes of the body*, the intimate texture of the brain, the theories of generation, and other wild and mystical subjects which human reason will probably never compass*.

But although we reject the conclusions, we cannot overlook the facts on which these abstract metaphysical notions have been founded. If it be true that the chick at an early period of its growth possesses a bronchial as well as pulmonary system, what a mysterious structure is here unfolded! Why should the embryo of man, or of any mammiferous animal, possess, even at its earliest period of growth, the system of the allantois, and all the complicated apparatus of the omphalo-mesenteric vessels and vesicle: these are structures which are indeed essential to the growth and perpetuation of birds, but how of the mammalia? Not, surely, to enable the embryo to pass a few hours or a few days of its early existence, and yet this were a more rational opinion than to suppose all animated nature formed to undergo a metamorphosis as extensive as extraordinary, exceeded by no prodigy which imposture has detected or credulity believed: a metamorphosis embracing within the period of a few months the whole range of the animal creation.

With those who delight in metaphysical speculation, who find, as the phrase is, "*omnia in omnibus*," these abstractions and metaphysical fictions (for occasionally they are merely so,)

* The reading of the passage referred to in Galen, forcibly recalled to my recollection the education of the Edinburgh graduate, and the exhibitions these young physicians were fond of making in certain medical societies, which like the school to which they belonged, were once great, but are now are all but extinct.—*Troja fuit*.

speedily assume the form of well adjusted and confirmed theories, admitting, as they think, of "demonstration." The "creative idea," at whose object we can but guess, is laid down as a physical law, thoroughly investigated. The doctrine of "*formation arrêtée*" is a good doctrine in itself, and by it we may unquestionably solve many otherwise perplexing problems in physiology; and so also are the great doctrines of unity of organization; what I object to is their being mistaken for positive inductions derived always from physical facts. That some malformations may be so explained cannot be doubted, but there is no truth whatever in physics, that the human embryo is necessarily forced to pass through a series of metamorphoses whose outline embraces the vast range of living adult beings, prior to its assuming the human form; nothing of this kind can be demonstrated; and when the "malformation," or "deformation," of the human embryo is appealed to as a proof that such metamorphoses were contemplated, and such a scale of development ordered, to me it appears, with all becoming deference to the opinions of others, that these theorists confound the abstract theory of the creative idea, whose essence must be "unity of organization," with the proofs that such a "unity" exists: or, in other words, they offer the occasional production of forms in the human embryo resembling the brute as proofs that the embryo was passing through these forms; whereas such forms simply shew that the laws of deformation are regular; that living matter never runs into fantastic forms, but simply depicts forms already contemplated by, and embraced within, nature's great plan*.

But whatever be the view adopted with reference to these difficult physiological and psychological doctrines, it is known to all anatomists that in the higher orders of animals the sexes are divided so as to require two individuals to form the species and to perpetuate that species: it is also well understood, that in some classes of the animal kingdom the generative organs termed male and female exist in the same indi-

* I admit unhesitatingly that in the human fetus there are forms and structures which, when they persist to the adult state (the transcendental laws prevailing over the special) give to the human form a strong resemblance to some of the lower animals—the pelvis, for example.

vidual, and that yet the concurrence of two individuals is required to eternize the race; and lastly, that perhaps in some of the lowest tribes of animals, and seemingly in many plants, both kinds of organs are present and effective in one individual without the aid of another.

If, in this disunion of the sexes, nature had rigidly drawn the line of demarcation, if vestiges of both sets of organs were not found in each individual, no such inquiry as the present could possibly have been instituted. But anatomists of all ages have admitted the contrary, and to explain the appearances, whether common or uncommon, whether frequent or rare, whether regular or irregular, numerous theories have been devised. Some of these theories have imagined the fœtus to be at first of no sex, and this, I think, is the more commonly received one: others have imagined it to possess the elements of both sexes, but, by a strange inconsistency, have imagined the organs convertible into each other. Previous to considering the merits of these opinions, let us first proceed to determine, if possible, the following points:—

What are the essential female organs? What the male? And, What the condition of the fœtus in its earliest stages?

INTERRUPTED CIRCULATION.

To the Editor of the Medical Gazette.

SIR,

IN compliance with the request of some medical friends, I have consented to publish an account of my late serious indisposition, and of my perfect recovery from it, as an illustration of some remarkable properties in the mineral waters of Bath.

My case is not an uncommon one in very old people like myself, but I suspect that in many such it is conjectured to arise from organic mischief, when, in fact, none whatever is present.

The following case, however, will shew that even in the very advanced stages of life, the loss of vitality of the heart may be perfectly restored. But for how long a time, is quite another question.

About six years ago, being then in my 74th year, I was attacked by a

regular tertian ague, in consequence of exposure to cold and damp air, in autumn. The paroxysms were severe, although they generally terminated in the sweating stage in less than three hours. The disease yielded to the sulphate of quinine and a suitable diet. I suspect that I did not continue the use of the tonic long enough, for after every symptom of fever had subsided, I remained much enfeebled; but as my appetite, sleep, and all the functions, were now in good order, I attributed the sensation of great weakness to old age.

On examining my pulse one day (which I am not accustomed to do), I discovered that it was frequently interrupted, sometimes every 10th, 12th, 16th, or 20th pulsation, sometimes not oftener than once in every 40th or 60th beat. The intervals of pulsation did not occupy a space of time greater than what might have been filled up by two, or at most three, pulsations. I was free from every other untoward symptom, such as palpitations, breathlessness, or swelling of the feet and ankles. I slept without sudden alarm, and equally well on either side, and on my back. I therefore concluded that the interrupted circulation was the effect of general weakness, and I had again recourse to the quinine, a generous diet, and a few glasses of old port wine, attending, at the same time, as may be guessed, to the evacuations.

Although I soon felt better, that is, stronger, under this treatment, it did not cure the chief complaint, and I therefore resolved to go to Bath, and try its waters, knowing, from old experience in others, its cardiac virtues, that is, its specifically stimulating action on the heart.

On arriving in that city at the end of October, 1838, I laid my case before my good friends Dr. Barlow and Dr. James Watson, who agreed with me in my mode of considering it, and encouraged me to try the internal use of the waters.

I had not drunk them for more than three weeks when my pulse became perfectly regular.

I returned home in the spring of 1839, and from that time, until about six months ago, I enjoyed excellent health; but then I was again attacked with the irregular action of the heart, and in a more alarming degree than

formerly, for now the pulse was interrupted after every 2d, 3d, 4th, or 6th beat, and the sense of general weakness and languor was proportionally great: at no time of the night or day could I count 19 consecutive pulsations, and it is remarkable that the suspension of pulse was as frequent in a horizontal position, and even after food and wine, as at any other time.

To prevent any foolish conjecture or quibble, I ought to remark, that it was the action of the heart (the contraction of the left ventricle) which was interrupted, and not the action of the arteries, which seemed to be endowed with their natural elasticity.

Being now in my 80th year, I had reason to suspect some organic affection of the valves to be the root of the evil, and yet there were many good reasons for doubting this, which, as may be easily imagined, I fondly cherished.

When organic mischief is in progress either in the valves of the heart or in the aorta, it will generally be found that independently of an interrupted circulation, there are other very remarkable symptoms, such as occasional palpitation, and often a preternatural hardness or sharpness of the pulse, and also a prevailing want of rhythm, if I may use the expression, between any consecutive pulsations. I had none of these symptoms, nor any œdematous swelling of the feet and ankles; nevertheless I thought it prudent to have the heart examined by the stethoscope before I again tried the Bath waters.

I arrived in that city for the second time on the 17th of August last, and applied to my friend Dr. James Watson, who I knew to be an expert and experienced explorer of the chest and its contents. After a patient examination, he pronounced the heart to be free from any organic derangement whatever, and consequently I lost no time in visiting the pump-room.

I began as formerly with a moderate quantity, namely, 4 ounces every morning at 7 o'clock, but I soon increased the quantity to 12 ounces twice a day, namely at 7 o'clock A.M. and half-past 2 o'clock, P.M.

At the end of the first week my pulse was greatly improved, and before three weeks had elapsed there was not a single interruption to be discovered in it either by Dr. W. or myself, and from that time to the date of this letter the

same regularity of the heart's action has continued.

When we reflect how very small is the quantity of carbonate of iron, and the other saline ingredients, of the Bath waters, we may well wonder at their stimulant properties.

Professor Daubeny has, I believe, detected a trace of brome in them, but I do not know any facts which prove what are the properties of this elementary substance except as a virulent poison, and I am much inclined to think, that some hitherto unknown principle, probably of a very volatile kind, will hereafter be discovered in these waters, for their effects in different maladies are inexplicable by the knowledge we possess at present of their mineral contents.

Iodine has been detected in them by Mr. Cuff, a chemist of Bath, but the largest quantity of that substance which Professor Daubeny discovered in any of the mineral springs of the south of England did not exceed a single grain in ten gallons of water. Now it is scarcely to be credited that the virtues of the Bath waters as a stimulant can depend on so small a quantity of this subtle agent, especially when it is considered that from 12 to 16 ounces of the water is the largest quantity which is commonly drank either in the morning or the afternoon.

Before I close my letter I wish to make one observation, which I deem of importance to a numerous class of invalids, especially as I do not think it has been insisted on by any of the numerous writers on the Bath waters.

It is the fashion to frequent that city for the purposes of health, only in the spring and autumn; this I consider as a practical error, for I am persuaded that a short summer course of the waters would be found more effectual, inasmuch as they could be drank at an earlier hour, and in larger quantities, in the summer, than during our cold springs and autumns.

I am aware that there is a fashionable prejudice against this opinion, which will not be easily overcome. This city, particularly the lower part of it, is said to be too hot and oppressive for a summer residence, and yet many of those who think so go to the valley of Baden Baden, where the summer heat is comparatively greater; but then it is the fashion to go there,

which explains why it is medicinally better! I do not believe that in any part of England, except on the tops of Welch, Westmoreland, or Scotch mountains, a freer or purer atmosphere can be found than in the upper parts of the city of Bath. Until it is frequented during the summer, by those who stand in need of its celebrated springs, their virtues will never, in my opinion, be fully appreciated.

I am sir,
Your obedient servant,
A. CRICHTON.

Seal Grove, near Sevenoaks,

publicum sit, dicendi periculum non recuso."

CICERO.

MEDICINE IN HINDOSTAN.

OUR Indian empire presents at this time a most interesting spectacle. While, on the one hand, the old fondness for territorial acquisitions still remains, strong as in the days of Clive or Wellesley; on the other, a new feature has sprung up, unimagined in their time—the education of the native youth in the learning of Europe. The probable effect of this great measure upon Indian politics, and the general condition of our eastern fellow-subjects, it is not our present purpose to investigate. It will be sufficient thus to have glanced at it, ere proceeding to a brief exposition of the present state of medicine in Hindostan, and of the most recent additions to the stock of medical knowledge, for which we stand indebted to our brethren of the East. A volume which we have recently received* will supply us with the requisite details; and it cannot but be use-

ful to watch the advances of medical science in the East. The influence of climate on disease is a subject pregnant with interest to the pathologist; and a city like Calcutta, rivaling London in the amount of its population, affords the amplest opportunities for the display of surgical skill.

Little more than twenty years ago, the native population of India were compelled to surrender themselves in sickness to the ignorance and chicanery of quacks and conjurors, whose miserable arts were the chief substitutes for medical practice in the East. In 1822, the Government of India became sensible of the necessity of some reform here. A certain number of natives, therefore, were directed to be trained up in the medical profession for the use of the state, in an institution devoted to that purpose. They were taught by means of translations and *viva voce* instruction in their own language. Very little good, however, was effected by these means. The acquirements of these young men proved to be very imperfect; and such as they were, the advantages derivable from them were confined to the military and civil departments of the East India Company. The great mass of the population, who stood the most in need of assistance, derived no benefit whatever from the system of medical instruction then pursued.

So prominent, indeed, were the defects of this arrangement, that in 1835, Lord William Bentinck, convinced of its inadequacy to the wants of that rapidly improving country, determined to form another institution, wherein native youths might pursue the study of medicine with all the advantages of an European system of instruction. This institution was so framed as to suit the wants not of the Government service only, but of the population at large. Its doors were to be open to the youths of all nations, natives as

* Transactions of the Medical and Physical Society of Calcutta, vol. viii. part 2. Calcutta, 1842.

well as foreigners, and the science of medicine was to be taught upon a scale commensurate with the magnificent objects in view.

Such was the basis on which the Medical College of Calcutta was founded. Its progress since 1835 has been in every respect such as might have been expected from the right spirit in which the measure was framed. It is dispensing far and wide the blessings of sound learning. Not only are the youths of the Indian peninsula there educated, but those also of Ceylon.

In the new Calcutta School of Medicine, the *English language* forms the medium of instruction, and the students are furnished with all the aids and appliances which the best regulated schools of Europe possess. Lectures are regularly delivered upon every branch of medical learning, with the exception of midwifery. This exception is made in deference to the peculiar customs and prejudices of the people. Practical anatomy is pursued with a degree of zeal and diligence which would do honour to Gower Street or King's College. The students are young men of good general acquirements, chiefly Hindoos, of all castes, including Brahmins of the highest rank; but besides them, there are several youths born of European parents in India. The industry and intelligence of the whole body of students are very conspicuous, and fully equal to the opportunities of instruction afforded them.

It requires but little foresight to estimate the consequences. From the walls of this institution there will issue annually, from this period, a gradually increasing band of intelligent and well-informed practitioners, who will spread over the country, and in time banish the reign of empiricism and ignorance. The more sanguine may even anticipate the day when sur-

gery and medicine may be enlightened by the labours of black doctors; when the vigour of Asiatic genius shall revive, and burn with more than its early splendour; and when "wise men from the east" shall again be seen in the cities of the west.

An institution for the education of the native youth in medicine has lately also been established at Madras, and the accounts which we have received speak in high terms of the progress there made by the students. The Madras institution, however, is more limited in its nature and objects than the College of Calcutta. The education afforded to the pupils is less comprehensive, and it is destined exclusively for the uses of the state. We may hope to see it, however, gradually enlarging its sphere, so as to become generally useful for the amelioration of medical science among the native subjects of that presidency. We presume that Bombay will not long allow itself to be distanced in the career of scientific improvement.

The fruits of the new system have not yet been tasted in the shape of an "Essay on Cholera," by Uma Churn Sett, Esq., or "Observations on the Cannabis Indica," by Dwarkanauth Goopto, Esq.; but the time is not far distant when these things will happen. Both these gentlemen are members of the Medical and Physical Society of Calcutta, which is an institution from which a long series of most valuable medical papers have emanated, as all our readers must know.

Until we can gather information from our coloured brethren of the east, we must be content with such instruction as their masters, the professors in the Calcutta College, and their coadjutors, can give us.

Among the subjects on which the medical journals of the east may reasonably be expected to enlighten us,

the most prominent is cholera. The following is the latest information which we have been enabled to pick up on that highly interesting and curious disease.

Cholera prevailed in Calcutta with considerable severity in the early part of 1840. The prostration of the vital powers was most remarkable, even from the earliest periods. It was remarked that the greater number of the seizures took place at night, and that, in spite of every remedial measure that could be thought of, reaction never took place. The reported deaths by cholera, in the months of January and February 1840, were 1532. In the Howrah Hospital, out of 33 cholera cases treated, 16 died, shewing that no great improvement has taken place in the old methods of treatment. The chief novelty that we notice in this respect is the employment of the tincture of hemp, to which Professor O'Shaughnessy attributes the recovery of several Europeans. This remedy was given at first in two-drachm doses, one drachm being repeated occasionally as required. Several cases which appeared hopeless, the professor adds, were thus saved. Intoxication generally followed in a quarter of an hour after the first dose; vomiting and purging were almost instantly checked, and the patient slept for some hours. We regret to add that, at the Howrah Hospital, the same success was not experienced. Dr. Stewart speaks highly of the advantages derivable in cholera from friction with dry ginger powder. By absorbing the cold clammy sweat, it lessens the deadly coldness of the surface. It appears, too, to be beneficial, by stimulating the capillary circulation.

Dysentery is another subject on which our Asiatic brethren have had a too fatal experience. The loss which the European troops, particularly the 26th

and 49th Foot, experienced from dysentery in Chusan, is frightful. The details are furnished us by Mr. Hutchinson, of the Bengal Medical Establishment. The dependence of dysentery upon malaria is here manifested most unequivocally. Among the troops sent to Manilla, to try the effect of change of climate on the chronic forms of Chusan dysentery, the mortality was very great, though the weather was fine, and the sick were abundantly supplied with good bread and fresh meat. The only medicine that was found of the least service was the old-fashioned combination of calomel and opium (five grains of the former to one of the latter), taken twice a day. Of 209 men embarked, 85 died on the voyage. The virulence of the dysenteric miasm of Chusan seems to have bid defiance to all medicine. These cases of dysentery were mixed with a few of intermittent and remittent fever.

Some interesting particulars regarding the prevalence of small-pox in the East, and the diffusion of vaccination among the population of Calcutta, seem to us worthy of record, though the dates are not so recent as we could have wished. In the year 1838, Calcutta was visited by a severe epidemic small-pox, which proved fatal to very large numbers. Out of 828 fatal cases, visited and reported on the spot, 497 were males, 331 females. 253 were under five years of age; between 5 and 15, 282; between 15 and 25, 183; upwards of 25, 110; so that all ages were alike sufferers. The deaths by small-pox in that year were six per cent. of the total mortality. It is at any rate a curious coincidence, if nothing else, that London was visited by epidemic small-pox in that same year, and that the proportion of deaths by small-pox, compared to the total mortality, was here seven per cent.

Small-pox is not a constant disease

at Calcutta, but visits it, just as it does other large towns, epidemically. The demand for vaccine protection there, as here, bears a marked relation to the degree of alarm prevailing during the epidemic invasion. In the three years 1834, 1835, 1836, the numbers vaccinated at the Government Vaccine Establishment were respectively 36, 53, 16. Total in three years, 105! In 1838, the number vaccinated was 1507! The same thing happens in England, and must always happen, so long as human nature remains the same. Out of sight out of mind! It is only by having the bane before our eyes that we think of applying to the antidote. It is only by the occurrence of a bad fire that people are driven to ensure their houses.

We had intended to add some hints on the pathology of *coup de soleil*, but our space warns us to desist. Much, however, might still be gleaned from the rich field of "Medicine in Hindostan." We may be tempted some day to interest our readers in the matter of Indian surgery.

COMPLICATED MENSTRUATION,

AS ILLUSTRATED IN TWO CASES.

By W. DETMOLD, M.D. of New York.

CASE I. — The following case represents features as interesting in a physiological point of view, as they are perhaps of rare occurrence. I therefore do not hesitate to give it publicity, though I have myself only for a short period been an observer and eye-witness of the course of the disease. The medical attendants were changed several times during the illness of the patient, and having been myself called in consultation only in the latter part of it, I have been obliged to rely for the history of the case, previously to my seeing it, on the statement of the patient and her family, and of the physicians whom I found in attendance at the time. The case, however, has been seen by a large number of professional men of the highest standing in this city, and I myself had an opportunity of showing the patient to several medical men from other parts of the country; so that as regards

the correctness and truth of the history of the main and most interesting features of the case (and to those I shall limit myself here) there cannot be any doubt. As the repeated change of the medical attendants, and my only temporary observation of the case, make it impossible for me to give an exact account of the medical treatment followed during the different stages of the disease, and as I, besides, consider the case less interesting in a therapeutic point of view than in a pathological and physiological, I shall omit here the treatment entirely.

Miss R—, of this city, of dark hair and complexion, had, with the exception of the ordinary diseases of childhood, always enjoyed good health, and she was apparently of a robust constitution. When fourteen years of age her menses first appeared, without any disturbance in her general health; and after that time she regularly menstruated for about one year. On the 17th of April, 1842, during one of the menstrual periods, she had, at the same time, (according to her own and her family's statement), a bilious attack, with a severe sore throat. She had leeches applied to the throat, and was bled in the arm. Her menstruation stopped during the night succeeding the venesection, and the following morning the patient had lost the use of her left leg, which became very painful, and began to swell from the hips down to the toes. Simultaneously with the swelling of the leg, a singular symptom appeared. *The whole surface of the body became covered with black hair*, so that the arms, legs, and chest of the young lady looked more like those of a hairy man of forty, while the upper lip and cheeks were covered with a delicate dark down, as we sometimes see in young men approaching the period of puberty.

I saw the patient about three months after the commencement of the disease, which then had just passed its acmé, and found her in the following condition. Her whole body was very much emaciated, and her countenance bore an expression of suffering, which was increased to the highest degree by the mere approach of any person to the pillows on which her leg rested. On her upper lip and cheeks was the above mentioned down, and her chest, arms, and legs, were hairy as just described. The hair showed, however, much more on the sound leg than on the diseased one, for as the sound leg was emaciated almost to bone and skin, the hair on it appeared much more dense than on the other leg, the skin of which was in the highest degree of tension from the enormous swelling. The circumference around the knee was twenty-two inches, and the thigh and leg were swollen in proportion. The skin was neither changed in temperature nor colour; the swelling was neither

phlegmonous nor cedematous; to the touch it was solid, and felt like a plastic deposit; it resembled hypertrophia, and the whole limb presented somewhat the appearance of phlegmasia alba. Outside and above the knee was a superficial and limited fluctuation, which, on being opened, discharged for several days a moderate quantity of healthy-looking pus; and a similar fluctuation appeared a few weeks after directly over the patella. Both these abscesses were, however, in no proportion whatsoever to the size of the leg, and they seemed altogether secondary, that is, not connected with the *causa proxima* of the disease, but rather consecutive upon the enormous swelling. The patient suffered intense pain from the slightest attempt at moving the limb, over which she herself had no control at all. She had two large ulcers from decubitus over the os sacrum, and the pulse was about one hundred in a minute, having been a few days previously as high as one hundred and twenty. Her appetite was good, and altogether the disease, as already stated, seemed to have passed its acmé; for the patient began gradually to improve, the pulse became daily less frequent, the swelling of the leg diminished by slow degrees, the limb became daily less painful, the ulcers on the back healed up, and about four months and a half after she was taken ill, she began to move about upon crutches. The unnatural growth of hair upon her body and limbs gradually disappeared, and about six months from the commencement of the disease the menses made their reappearance. From that time she continued to improve steadily, and she is now, in June 1843, a fine hearty-looking woman, with no remains of her extraordinary illness, except a false anchylosis of the knee-joint, evidently caused by plastic deposit in soft parts and ligamentous apertures around the joint. Otherwise she has the full use of her limbs, with the exception that after much exercise she has a feeling of fatigue in that leg, and it becomes slightly cedematous.

I have thus given only, as I premised in the beginning, an outline of the characteristic features of the case, without entering into the minutes of the daily changes even at the period when I had the opportunity of doing so; and I will now, in conclusion, only state that the application of ice to the swollen limb seemed to have been the most beneficial remedial agent resorted to. I also abstain from commenting on the physiology and pathology of the case, which seem, as far as the growth of the hair is concerned, a mistake of nature in anticipating the period when menstruation ceases naturally.

CASE II.—As I have given the above case mainly on account of its pathological and physiological interest, without reference

to therapeutics, I do not deem it out of place to add the following case, of which the principal interest lies perhaps in the therapeutical treatment pursued.

Mrs. —, of this city, of lymphatic temperament, had, until her marriage, which occurred when she was very young, regularly menstruated. She has now been married eight years. Soon after her marriage, her menstrual functions became deranged, the pain at each period being so excessive that she had invariably to keep her bed for about a week. The pain and uterine spasms were at times so violent as to produce convulsions; and, withal, she never lost more than a few drops of blood during the first few hours of each menstrual period. She had never, during the eight years of her matrimony, been pregnant. She had been under the care of several medical men, and she had at different times been put under the influence of various remedies, as well for momentary relief during the paroxysms of her menstrual spasms as in the interim for a radical cure. It was all, however, to no good effect, for she only obtained temporary relief from copious venesections which were repeated every few months.

In August, 1842, she applied to me for relief. Besides her regular attacks of illness, every four weeks, she complained of a continual feeling of soreness above the os pubis, which was much increased by intercourse with her husband. I proposed, and she submitted, for the first time, to an examination per vaginam. The collum uteri felt rather large and soft; and when the speculum was introduced, the labia of the os tincæ showed a dark purple colour. I repeated the examination at her next menstrual evacuation, and found the same appearances as before, only stronger marked, showing evidently a high degree of venous congestion. I advised the immediate application of six leeches to the os tincæ. The after bleeding was very copious, so much so that her husband became alarmed during the night, and sent for me to stop it; but as I found it not excessive, I allowed it to continue for several days. I did not ascertain whether the blood flowed from the leech bites or from the interior of the uterus. The patient, however, had neither pain nor spasm of any kind, during the menstrual period, being the first time in about eight years. I ordered the application of the leeches to be repeated every month, upon the first warning of the approaching menstruation, and each time with the same beneficial result. Besides, I ordered, during the intervening time, injections of cold water per vaginam, and advised abstaining from intercourse with her husband. At the same time, I prescribed a simple and healthy diet, with exercise in the open air; and as the patient was evidently

doing well under this treatment, I did not deem any medicine necessary except keeping her bowels regular with small doses of rad. rhei. This course of treatment was carried on for about four or five months, the leeches having been applied four times, when, as the soreness over the os pubis had long since entirely disappeared, the patient did not deem it necessary to have them applied a fifth time; and the result was, to her great surprise and delight, a regular menstruation, without the least pain, a sufficient quantity of blood being lost without the leeches. At her next term, she had again a regular menstrual evacuation, and immediately after that, she must have conceived, for she began to complain of sickness at the stomach in the morning, exhibiting, in a word, all the usual symptoms of the early stage of pregnancy. Her menses now stopped for three months without any disturbance in her general health; but, unfortunately, a few weeks ago, in consequence of imprudence in taking a great deal of exercise, and a long ride in a jolting stage, she had a miscarriage, discharging a perfectly normal and well developed ovum. Since then she has had a regular and sufficiently abundant menstrual evacuation.—*The New York Journ. of Med. & Collateral Sciences.*

COPPER IN ORGANIC TISSUES.

M. JULIUS ROSSIGNON, of Lyons, has lately addressed a communication to the Academy of Sciences, on the presence of copper in the organic tissues of a great number of vegetables and animals.

It is well known that MM. Danger and Flandin have endeavoured in their last memoir to establish the non-existence of copper in the human body in its normal state. M. Rossignon proposes in his note to contradict their results, and to confirm the existence of copper in the healthy human body.

His experiments show that copper exists not only in the blood and muscular fibre of man, but in a great number of domestic animals, and in the vegetables on which they feed.

Experiments made on dogs in 1839 showed that copper existed in them. M. Dumas having mentioned in his lectures, that wheat contains an appreciable quantity of copper, which is absorbed by our digestive process, M. Rossignon was induced by his knowledge of this fact to continue his researches on the normal existence of copper in organised beings, and particularly in the alimentary substances most used by man.

The following are some of the results to which M. Rossignon more particularly directs our attention.

The *gelatine* obtained by the philanthropic process of the *hôpital St. Louis*, when carbonized in a close vessel, affords 0.03 of pure copper in 100 parts of carbon.

The *boiled sorrel* of the green-grocers affords as much as two per cent of the neutral oxalate of copper.

Munier chocolate affords carbon containing 0.07 of copper.

Marquis chocolate affords only 0.05.

Bread from the principal bakers in Paris gave from 0.05 to 0.08 of copper in 1000 parts of carbonized bread.

Coffee contains a few atoms of copper.

Succory affords more.

Madder contains a considerable quantity.

Sugar affords a carbon, which, when rigorously analysed, furnishes copper, and sometimes lead.

Barley-sugar affords copper.

Fecula sugar, when carbonized, contains as much as four per cent. of copper.

Lastly, M. Rossignon says that since reading the memoir of MM. Danger and Flandin, he has found very small but appreciable quantities of copper, in human semen, in the excrements of fowls, in eggs, and in the eye of the ox completely calcined in a close vessel.—*Gazette Médicale.*

EFFECT OF THE ANISODUS LURIDUS ON THE PUPIL.

By DR. LEJEUNE.

THE *Anisodus luridus*, a perennial herbaceous plant belonging to the natural family of the *Solanaceæ*, was brought from Nepal to Europe in 1824. In our gardens it often does not come out till the middle of June; it then springs up with astonishing rapidity, and soon surpasses the *Atropa Belladonna* in height. It strikes its root deep into the ground, and withstands the severest winters. It is of a pale green colour.

A tincture prepared with an ounce of the dried leaves to eight ounces of alcohol at 20 degrees*, when given to different patients, produced an extreme dilatation of the pupil; the highest dose being twenty drops in the 24 hours. Two of them suffered from amaurosis for a short time, and their blindness did not go off till the medicine was omitted.—*Gazette Médicale*, Nov. 4, 1843; from the *Journal de Médecine de Bruxelles*.

INFREQUENCY OF PHTHISIS IN MARSHY COUNTRIES.

At the meeting of the Academy of Medicine, on the 7th of November, a letter was read,

* Perhaps 20 deg. on Baume's hydrometer, equal to *Spiritus tenuior*, or proof spirit.—*Translator's Note.*

addressed to the President by M. Nepple, on the infrequency of phthisis in marshy districts. After being read by the secretary, it was referred to the committee appointed to inquire into the antagonism supposed to exist between phthisis and marsh-fevers.

M. Olliver (of Angers) requested the attention of the Academy to this letter, which seemed to him to contain important facts. It confirmed what Brera said, some years ago, on the infrequency of phthisis in Venice, which he, too, attributed to the emanations from the lakes.

During Dr. Olliver's stay at Venice, he endeavoured to verify this fact; and he found that there were not more than seven or eight phthisical patients among twelve or fourteen hundred annually admitted into the hospitals of the town. Almost the whole of the remainder were suffering from intermittent fever or rheumatism.—*Gazette Médicale*, Nov. 11, 1843.

NAPHTHA.

To the Editor of the Medical Gazette.

SIR,

MR. PROCTOR's letter on the curative effects of naphtha, in the *MEDICAL GAZETTE* of Nov. 17, leads your readers to infer that the "case" he details was *rejected* as consumptive at the Colchester Hospital.

We beg to state, that no individual bearing the name of "Charles Perry" has presented himself for admission to this institution.—We are, sir,

Yours faithfully,

E. WILLIAMS, }
R. CHAMBERS, } Physicians.

Essex and Colchester Hospital,
Nov. 20, 1843.

ST. GEORGE'S HOSPITAL.

WE regret to learn that the state of Mr. Babington's health compels him to resign the office of surgeon to St. George's Hospital. This causes a double vacancy; the assistant-surgeon, almost as a matter of course, becoming surgeon, so that the real vacancy is in *his* appointment, for which a very active canvass is now going on.

MIDDLESEX HOSPITAL.

DR. WATSON has resigned the office of physician to Middlesex Hospital, in which he will, it is to be presumed, be succeeded by Dr. Crawford, the assistant physician, in whose office a vacancy will thus occur.

CLINICAL REMARKS

UPON A

CASE OF HEPATIZATION OF THE LUNG,

Delivered at St. Thomas's Hospital,

By Dr. BARKER.

THE following case is a good example of the extent to which the healthy structure of the lung may be restored, after it has been hepatised by inflammation.

Anne Muttock, ætat. 26, a servant, was admitted into Anne's ward on the 13th of April, 1843. Complexion fair and florid, skin soft and thin, lips thick, and the general appearance that of a strumous person, though there were no signs of scrofulous disease. She was discharged from a surgical ward about a month ago, having been long affected with abscesses about the left knee—not, however, affecting the joint itself—which were healed, but the cicatrices impeded the movements of the limb.

Three weeks before her admission she was attacked in a manner which she did not describe very precisely or intelligibly; but, it appears, she had rigors, followed by slight febrile heat, and dyspnoea; and the left side soon became painful below the mamma. She took medicine by direction of a medical man; but, apparently, the treatment had not been active: she was not bled, and the medicine produced no effect but purging.

When first examined by me, she lay a little towards the left side; but could lie, for a short time, on the right side, without inconvenience. The breathing was slightly hurried whilst she was at rest, but hardly amounted to dyspnoea, since it caused no inconvenience to the patient; very slight exertion, however, rendered it distressingly rapid. There was frequent, short, hacking cough, without any expectoration or pain in the chest. She had lost flesh since the commencement of the illness, and com-

plained of night perspirations. The pulse was rapid, small, and feeble. The legs became oedematous if she remained long in the erect position. The chest was well shaped. On drawing a full inspiration, the left side was not so fully expanded, whilst, on making a complete expiration, it was not so much contracted, as the right. The sight alone, then, was sufficient to prove defective respiration on the left side; and, as no cause for this could be detected in the form of the chest, it was probable that the lung was either partially impervious to air, or that the pleura was distended with fluid. On percussing the right side of the chest, it appeared naturally resonant in every part, and the respiratory murmurs were healthy, and very loud. The left side, on the contrary, was uniformly and extremely dull on percussion at every part, except for about an inch and a half below the clavicle; and, even in that spot, it was much duller than the corresponding part on the right side. Over the same space indistinct vesicular respiration could be heard; but, in every other part of the left lung, in place of the gentle, rustling sound, caused by the expansion of a healthy lung, was heard the harsh, blowing noise, called tubular or bronchial respiration, caused by the sound made by the air passing along the bronchial tubes, which is deadened when the lung is spongy and healthy, but is conveyed to the surface, and easily perceived by the ear, when the bronchial tubes, remaining pervious, are surrounded by consolidated lung. The voice, also, could be heard on applying the stethoscope to many parts of the central, and even of the lower, portions of the left side of the chest—not passing distinctly through the tube to the ear, as in pectoriloquy, nor reaching the ear in that less distinct manner called bronchophony; but there was a confused inarticulate sound of the voice, such as is heard when the smaller bronchial tubes are surrounded by condensed lung.

My diagnosis in this case was, that the

whole of the lower and middle parts of the left lung were in a state of red hepatization, the result of inflammation occurring three weeks before.

As a correct diagnosis in this case was absolutely necessary, before any rational plan of treatment could be adopted; and as the treatment pursued, would not only have been incorrect, if the obvious want of respiration had depended on other causes than that stated; but would also have been useless and injurious, if the consolidation of the lung had depended on an attack of inflammation of much longer standing than this patient's recent illness; I shall shortly consider the grounds on which my diagnosis was formed, and the objections which may be made to its correctness.

In the first place, it may be thought that the symptoms complained of by the patient, at the period of her first attack, were not sufficiently severe to indicate an attack of pneumonia, so extensive as to affect the whole of one lung. She appears to have had rigors, followed by slight feverish symptoms; some cough, but no expectoration; pain under the left mamma, not very severe; and to have gradually fallen into the state in which she presented herself at the hospital. Although it is now known to all intelligent practitioners that pneumonia is a disease which, notwithstanding its inflammatory nature, and the importance of the organ affected, is often not made manifest by any very prominent symptoms—and that cough, dyspnoea, pain, expectoration, and fever, though often present, and characteristic of the disease, are often wanting, or imperfectly developed—although these facts are known and admitted, the knowledge is often not acted upon—in some cases it is, perhaps, not possessed—and practitioners are too apt to take for granted, that, because the obvious symptoms of chest disease are slight, the disease must necessarily be some mild form of bronchitis or catarrh; and thus pneumonia not unfrequently makes great progress before its first stage is even suspected. Even the expectoration, which, when present, is so decisive a proof of the existence of the disease, is not unfrequently wanting; and the augmented rapidity of the breathing, which is rarely absent, may cause so little inconvenience, and give rise to so little labour in the respiratory movements, that it may be denied by the patient, and not attract the attention of the medical attendant, unless the respirations are counted. I have no doubt the case under discussion was such an one. It must be evident, from the mild remedies, apparently cathartics only, which had been employed, that the nature of the disease had not been suspected before the patient came to the hospital.

The absence, then, of any urgent symp-

toms at the first attack, or up to the period of admission, cannot be looked upon as any proof, not even as presumptive evidence, that the disease was not pneumonia.

But the lung might have been rendered impervious to air without pneumonia, and there might have been an accidental febrile condition at the time from which the illness was dated, independent of disease of the chest. Was there any thing, then, in the state of the chest itself, to lead us to suppose that it had been affected with pneumonia? The lung might have been rendered equally solid by tubercular matter: but, whatever had rendered the lung impervious to air had affected nearly the whole of one side, and one side only: and it is in the highest degree improbable, 1st, that one lung could be rendered completely solid by tubercle whilst the other side remained sound; 2d, that the only part of the affected lung, in which there was an approach to healthy respiration, should be the upper lobe—the part in which tubercular matter is almost always first deposited; and 3d, that there should be so extensive a deposition of tubercular matter, without the slightest sign of any part of it being softened, as was evident from no crackling sounds being heard in any part of the chest. These proofs of the solidification of the lung not depending on tubercle, far outweighed any slight presumption, of the existence of tubercle, which might arise from the commencing emaciation, the night perspirations, and a slight hectic flush perceptible in the afternoon. Moreover, the disease was scarcely of sufficiently long standing to countenance any suspicion of tubercle being formed in sufficient quantity to cause complete solidification; for I had ascertained, at the time of her previous residence in the hospital, when she was, in the first instance, my patient, that the lungs were sound. A correct opinion on this point was the more necessary, because the administration of mercury, subsequently adopted with great benefit, would, in all probability, have greatly hastened a fatal termination if there had been tubercles in the lungs.

Neither was it probable that the solid mass in the left side of the chest was any other kind of morbid growth, for all such growths in the lungs, except tubercle, are comparatively rare; if they had existed extensively on one side, the other would probably not have been free from disease; if sufficiently large to *fill* one side of the chest, they would probably have pushed the heart out of its place (which was not the case); and if sufficiently extensive to cause universal dulness and want of respiration, they would have obliterated the bronchial tubes so completely that tubular respiration could not have been heard so distinctly as it was in this woman.

The lung, however, might have been compressed by pleuritic effusion, and in that case there would have been the dulness on percussion, and absence of respiratory murmurs, which were observed in this woman. But *tubular* respiration could be heard over the greater part of the affected side. Now, if there had been effusion so slight in extent as to allow tubular respiration to be heard at the lower parts of the chest, it must have been so limited in quantity, that, whichever part of the lung might be uppermost, according to the position of the patient, would have been distended with air, and come in contact with the ribs; and, consequently the point at which respiratory murmurs could be heard, and a moderately clear resonance obtained by percussion, would have varied as the patient changed her position. Such, however, was not the case; since, whatever the position of the patient, respiration could be heard, and a clear resonance obtained by percussion, only beneath the clavicles.

These symptoms affording conclusive proof that there was not pleuritic effusion, I need not dwell upon the absence of other signs, which would have been sufficiently evident, had there been any large quantity of fluid in the pleura.

You see, then, that the history of the case was in no way opposed to the supposition, that the febrile attack, three weeks before Nuttall's admission, had been pneumonia: on the contrary, the symptoms of that attack, as far as they could be ascertained, were favourable to such a supposition. The state of constant semi-expansion of the left side of the chest, with slight movement either on inspiration or expiration; the dull sound on percussion; the absence of respiratory movements; the existence of tubular breathing in the solid parts; and the confused, muttering sound of the voice at the same parts, were all symptoms which would, of necessity, attend extensive hepatization of the lung; there was a degree of probability, amounting almost to certainty, that the solidification of the lung was not caused by tubercle, or other morbid growths; and it was quite certain that no extensive pleuritic effusion existed: on these grounds I founded my diagnosis.

It was certain, also, that the hepatization must be the red kind of that change of structure; for, if it had been of the kind in which pus, and matters which ultimately become softened and broken down, are infiltrated in the substance of the lungs, and air vesicles, there would, at this period of the disease, have been expectoration; and crackling sounds, caused by air passing through pus, and other fluids in the bronchi, &c. would have been heard distinctly.

At the time, therefore, when this patient came under my care, I had reason to believe the lung had been inflamed, and its vesicular

structure temporarily destroyed by effusion of organisable matter into the parenchyma of the lungs, and the air cells, and by thickening of the walls of the latter; for I believe all these changes contribute to the solidification of the lung in such cases.

It can scarcely be necessary to say that such a state of lung ought to be remedied, if possible; for, although persons with extensive disease of this kind, may appear to enjoy good health; and, when tranquil and at rest, may not seem to suffer from chest affection, there can be no doubt they are less capable of bodily exertion than others; and the danger of even slight disease would be great, if the remaining healthy portion of the lung ever became affected. Moreover, I believe lungs thus permanently affected are more liable, than healthy lungs, under favourable circumstances for the formation of tubercular matter, to become the seat of that disease.

To promote the absorption of the effused matter which obstructed the lung, I determined to put the patient under the influence of mercury; and for that purpose ordered—Hydrarg. Iodidi gr. ij. ter die. Bleeding would have been employed had there been any signs of plethora; but the pulse, though rather quick, was small and soft; the skin was constantly moist; and at night there was said to be free perspiration. In consequence of the iodide producing irritation of the stomach and intestines, two days afterwards I substituted

Hydrarg. c. Cretâ gr. v.; Pulv. Ipecac.
Comp. gr. iiss. 6tis horis.

This produced its full effect upon the mouth by the 25th, six days after the mercurial was commenced; and it was then so managed as to keep the mouth moderately tender until the 6th of May, by giving it every night, or every second night. Whilst the mercury was producing these constitutional effects, the lung was examined carefully about every other day. No change took place until two or three days after the mouth was affected; but, at my visit on the 29th of April, ten days after the mercurial treatment was commenced, and about five after the mouth became sore, improvement in the lung was first perceived. The dulness on percussion remained unchanged, and little more than tubular respiration could be heard, except at the uppermost part of the chest, where respiratory murmur had been indistinctly heard from the first. Nevertheless, it was evident that more air was entering the diseased lung than when the treatment was commenced. It is difficult to describe the sounds through which I came to this conclusion, because they could still only be called tubular; but every one who examined the chest agreed with me that more

air now entered the left lung, at each inspiration, than when the patient was admitted. The favourable change went on; and, by the 6th of May, sibilant rhonchi could be heard in several parts, especially at the lower, lateral, and axillary regions, indicating that the smaller tubes were becoming pervious to air. At the same time I thought, but it was impossible to feel certain on such a point, that a somewhat less dull sound was elicited by percussing the same parts. At this time I determined to avail myself of any power, which Iodine might possess, of promoting the absorption of the products of inflammation, and ordered—

Potassii Iodidi, gr. v.; Potassæ Bicarbonat. gr. xv. ter die ex Infus. Gentian. C.; and, to keep up the action of the mercury, Hydrarg. Iodid. gr. ij. alt. noct.

This mixture was continued until she left the hospital; the mercurial was so managed, in quantity, as just to keep the mouth tender.

The chest was examined so frequently, that slight changes could not well be noticed; but, at the period of this patient's discharge from the hospital, on the 17th of June, when no apparent change had taken place in the lung for at least a fortnight, she was in the following condition. The health and strength had improved, and much flesh had been gained since her admission. There was much greater equality between the two sides of the chest, as regards their expansion and contraction, at each inspiration and expiration. There was great increase of the resonance of the chest on percussion, at every part, especially in the subclavian, mammary, axillary, and lower lateral regions. To such an extent, indeed, had this improvement taken place in some parts, that if the left side alone had been percussed, and no comparison had been instituted between it and the right side, little notice would have been made of its dulness. And this, I may observe, is a good illustration of the necessity, in many cases, of trusting to a comparison between the two sides of the chest, rather than to the absolute dulness and indistinctness of the sounds observed on one. The sounds of respiration had improved in the same degree. The tubular sounds had vanished, except at the lower dorsal region, and at the lower part of the space between the scapula and spine; and, in its place, could be heard slight sonorous and sibilant rhonchi, and respiratory murmurs varying from very faint and indistinct vesicular respiration, to what would have appeared almost healthy, but for a comparison with the opposite side. The respirations had become natural in frequency, and there was no dyspnoea.

That this patient was in a far better con-

dition when she left the hospital than when the treatment of her case was commenced, cannot be doubted; but it may be questioned whether the improvement was owing most to medicine, or a natural process which would have taken place under any circumstances. And this question is one of importance; for placing a person under the full influence of mercury, and keeping her slightly in that condition for four or five weeks, with little intermission, must be injurious, when not specially necessary, not only in its immediate action, but in its more remote effects. You all know that, when external parts are inflamed, and resolution takes place, the matters which have been effused into the inflamed part and surrounding cellular tissue, often remain unabsorbed for a considerable time after the inflammation has subsided, but ultimately disappear without any remedial agent being used. On the other hand, it is equally well known that they do not always disappear spontaneously; that mercury and iodine have both considerable powers of hastening their removal; and that this power is much less in the case of inflammatory products, which have been long formed, than when they are recent. When the lung is the seat of disease, its restoration to a state of health is a matter of such vast importance, that it cannot be considered safe or judicious practice to wait for the chance of a natural cure, when we are possessed of agents capable of promoting that cure, merely because their use is attended with certain minor evils; and the necessity of making use of such means early to promote a cure, is the more evident, when we consider that, if the natural cure does not take place, any delay will greatly diminish the chance of good arising from the use of remedies. If we carefully examine the case under discussion, we shall see little reason to suppose that the mercurial treatment was uncalled for, or that the patient would have regained her present state of health if left unaided by medicine. The acute stage of the disease had ceased, in all probability, a week or ten days before her admission into the hospital; the lung was as solid as it could be from hepatization; there were no symptoms of a favourable change going on in the chest; after her admission she remained some days without perceptible alteration; it was not until the system was completely under the influence of mercury, that any proof of absorption in the lungs was evident; and it was some days later before the improvement became considerable. So far, then, as one case can prove anything, we have good evidence that the treatment adopted was not only useful, but necessary.

But it is not on the evidence afforded by this case alone that I rely. I have seen

many such cases—cases in which there was good reason to believe a part of one or both lungs was hepatized, and the disease had become stationary. In these cases mercury was administered; and, when its effect on the system was manifest, then the first beneficial change began in the diseased lung. Four cases in which the lung had become extensively hepatized, and all acute disease had ceased before the patients came under my care, have been treated by myself; and I have seen others. In two of my own cases the improvement was very great; in one it was slight, and in one no change took place.

After what interval are we to abandon all hope of being able to improve the state of a hepatized lung, by the use of mercury or iodine? On this point I can give no precise information. In one case which I saw much benefited, the patient had been convalescent from the acute disease at least five weeks; but, if well assured that any consolidation, which I might discover in a lung, was the result of pneumonia, and there was no reason to fear the presence of tubercles, I should be disposed to try the effect of mercury and iodine at a much later period.

I cannot conclude my observations on this case without noticing the want of some of the signs, which you will find set down in books, as always indicating the return to a state of health when the lung has been hepatized; viz. that on the decline of the disease you hear all the stethoscopic sounds reversed, or in the contrary order to that in which they had been heard as the disease advanced; and, consequently, when the lung has nearly recovered its healthy condition, you again hear the small crepitating rattle, and may again have the characteristic expectoration of the early stage of pneumonia. This, no doubt, sometimes takes place; but, in at least one-half of the cases of recovery from hepatization, which have come under my own notice, there has been little expectoration, and very little, if any, crepitating rattle. In judging of the progress the lung is making towards recovery, I am accustomed to rely principally on the sound of tubular respiration becoming less loud, the gradual coming on of sibilant rhonchus, and both these sounds being ultimately deadened as vesicular respiration begins to be re-established. If the small crepitating rattle is heard, and tenacious expectoration comes on, after hepatization of a portion of lung, they are undoubtedly very good signs; but you must not suppose that recovery cannot be going on favourably, merely because you do not observe these symptoms.

CONTRIBUTIONS TO ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

[Continued from p. 281.]

(For the London Medical Gazette.)

Hermaphroditism: a Memoir read to the Royal Society of Edinburgh in 1827 and 1828.

PART III.

THE organs essentially female are, first, the ovaries; secondly, the fallopian tubes; thirdly, the uterus; fourthly, the vagina. Now of these organs we find no analogous structures, nothing corresponding to them in form or function, in the male. All the rudiments of these organs, if they ever existed, have completely disappeared in the male; but they occasionally leave traces of their influence not to be mistaken, and to which we will presently revert. The other generative organs found in females are the labia majora, labia minora, clitoris and prepuce, rudiment of the cremaster, round ligament of the uterus, broad ligament of the uterus, glands of Cowper, and gland surrounding the neck of the bladder; to these we may add, in some animals, portions of the vasa deferentia. The glands of Cowper are common to both, being also equally developed.

Most anatomists admit that, at a very early period of the female fœtus, the ovaries present an entirely different shape, and seemingly also structure, from what they afterwards assume; independent of their great comparative size and length, there is connected with them a series of vascular looking tubes, which seem to me the remains of the male testes. I have observed these tubes now for a very long period, but could not hitherto determine their nature, until accident put into my possession an anatomical preparation, proving them to be the remains or rudiments of the testes. Moreover, that the ovaria can have nothing analogous to them in the male structure may be inferred, I think, from their structure; from their occasional presence, together

with the testes, in the same individual; from their presence, when fully developed, deeply influencing the whole economy, producing a condition of the body purely female, as opposed to the male in all respects, and maintaining these differences so long as they maintain their influence; from the nature of the tube conveying the product of their secretion towards the uterus never being continuous, in any animal whose structure is known to me, with that of the ovary; from the proofs I shall have the honour of submitting to the Society, that these tubes (fallopian), appendages of the ovary, are not analogous to the vasa deferentia of males, nor convertible into them; and finally, that they almost constantly co-exist in the females of certain animals, which co-existence necessarily excludes all idea of identity*.

From the ovaria the embryo is considered as being conveyed to the uterus by a tube termed fallopian; the ovarium, moreover, is secured in its situation by the broad ligaments and by its proper ligaments. The older anatomists, who dissected chiefly the bodies of the lower animals, mistook the *vasa deferentia*, which I shall afterwards show to exist in females of the animals which ruminate, for another set of vessels connected with the ovaria, which error, with a slight modification, has extended to the present day. The discovery of the exact nature of these vessels (ducts of Malpighi) sets aside for ever all the speculations of antiquity connected with this subject.

This notion, I may further observe, of many of the ancients, that there were two tubes connected on each side with the uterus, and which they supposed to lead either to or from it, led to singular errors, and was founded on singular errors; for, at first, it was not true, anatomically, that there existed in the human structure two tubes on each side of the uterus, and which lead to or from that organ, there being but one on each side—the fallopian tube; and though we might readily excuse the more ancient anatomists, as Hippocrates, Aristotle, and Galen, in their belief of such a doctrine, and in promul-

gating in their works that double tubes connected with the uterus exist in woman, to which they assigned whimsical, and in some measure contradictory functions, inasmuch as these anatomists were debarred the knowledge of human anatomy, and were consequently without that steady light which the investigation of human structure hath shed over all anatomical and physiological inquiry, we cannot so overlook the gross errors, and I may almost say wilful misinterpretation of structure, which we meet with in the writings of Wharton, and many others prior and posterior to his time, who obstinately insisted on calling the ovarian ligaments uterine tubes, contrary to the evidences of their own senses, which must have taught them that they were solid bodies, unfit to perform the functions they supposed them destined to. To Wharton, and many others of his day, the anatomy of the human body was sufficiently familiar, and therefore they need not have repeated this double error, or rather heaped error upon error, as they assuredly did. The ancients saw, in those animals which they generally dissected, two tubes on each side of the uterus, and the horns of the uterus running parallel with these organs, and had no idea that they possibly could be other than female parts, found, as they were, in connection with females and female organs anatomically, and associated with them by function; for the doctrines of final causes did not teach them that parts essentially male could exist in the female body. And, moreover, having their reason perverted and twisted with foolish notions about generation, superfetation, and the discharge of the seminal fluids from the ovaries, which they presumed to come into the vagina at a time when the external orifice of the uterus was known to be closed, they could hardly have formed any other notion of these tubes than that they were essentially female parts*.

* Bauhin, speaking of the fallopian tubes, which he always calls *vasa deferentia*, conformably with the prevalent notions of the nature of the seminal fluids and their course, says, "*vasa hæc deferentia ubi ad uteri latera pervenerint utrinque dividuntur et harum pars altera brevior sed amplior in sui lateris cornu medium locove proximo implantatur; pars vero altera quæ angustior est, sed longior secundum uteri latera ad ejus cervicem utrinque inter duas tunicas fertur et infra os interius sub cervice in*

* It were easy to accumulate proofs: when the ovaries are removed, and during the adult stage of life, the whole character becomes altered.—See Pott. When injured in birds, there is a change of plumage.—Hunter, Le Vaillant, Yarroud, &c.

Now the great error here was, first, in believing the ducts of Malpighi, as they were usually called, to lead to the ovaries, which they positively do not; and secondly, in supposing them to be present in all animals, and more especially in the human female. I cannot avoid, although it be digressing a little, pointing out in this place the mischievous tendency of presuming any thing to be true in anatomy which is absolutely opposed to the evidence of the senses, not to employ more severe language, or a harsher style of criticism: hence has arisen, I think, the evil report of physiology with many men distinguished for their liberality, for their soundness of judgment and precision, and who, from the possession of these very qualities, have raised well-founded objections to the general vagueness of physiological explanation, to the hasty deductions and ever-varying principles of physiology. But if we blame the older anatomists for their want of light and candour, touching their errors with a lenient hand, as we naturally overlook the foibles of the aged, we can hardly extend the same leniency of criticism to those who, as it were intentionally, heaped error upon error; to those who, like Wharton, not finding these ducts in the human female as they were known to exist in brutes, could yet, merely in support of their hypothesis, imagine the ovarian ligaments to be tubes; and all these ill-observed facts they connected and combined together with an ingenious sophistry, thus giving their doctrines a wonderful degree of plausibility. The female ovaries, to which they almost uniformly gave the name of testes, in consequence, chiefly, of their slight resemblance to the male preparatory organs; these organs they presume to be the secretory organs of the female seminal fluids; for they believed firmly that the fœtus was a product of a mixture of the male and

female seminal fluids in the uterus, which fluids they imagined to descend by one or other of the tubes we have already spoken of.

Casper Hoffman, in his *Institutiones Medicæ*, as quoted by Wharton, denied that the ovaries, or, as he termed them, testes muliebres, could be compared to the male testes: his arguments are, that they are small, juiceless, and are merely the cadavera testium, and he finally refuses to them any ducts by which their product, whatever it might be, could possibly be conveyed into the interior of the uterus. What functions this learned physician, and writer on the institutes of medicine, and founder, if my memory be correct, of the physiological system taught in the Medical School of Edinburgh for nearly a hundred years, assigned to the uterus, I do not pretend to know, nor think it worth while to inquire; for, like many physicians, as well prior to as since his time, Hoffman must have written much upon pure conjecture, and without the smallest reference to exact anatomy and careful observation and experiment.

The reasonings of Wharton in discussing these doctrines of Hoffman are most ingenious, and present us with a view of a style of physiological reasoning which has not yet, I fear, been altogether abandoned. Having determined in his own mind, and contrary to the evidence of his own senses, that there are two sorts of vessels on each side, leading from the ovaries to the uterus, he finds it necessary to devise different functions for them. Admitting that nature would not employ two organs, or two instruments, in accomplishing what might be effected by one — "*frustra enim sit per plura quod fieri potest per pauciora*:" — he goes on to state, that one ejaculatory vessel being sufficient for one ovary, it is probable that these different vessels perform different functions: "*et si alterum ejaculatorium fuerit, potius alterum esse receptivum.*" He is forced to admit, however, that the shorter duct, viz. the ovarian ligament, which he mistook for one, does not communicate by any open orifice with the uterus; but sophistry, never without a reason, leads him to assert that this is the very structure which he anticipated, inasmuch as the same thing happens in the seminal tubes of the male, which,

prostates inseritur quæ non ita ut in viris sunt conspicuæ: cum feminarum semen non sit copulentum: quæ semen ad tempus coitus conservant: et per hanc viam gravidæ in coitu non vero orificio uteri interiore reserato semen effundunt. (An vero hæc altera portio, a priore et vasculo uteri tubæ inserto et in uteri fundo simul junctis, producat, lactenus non licuit observare.)

"Cum enim facta conceptione," &c.

The tubes Bauhin speaks of here, and to which he ascribes such curious functions, are, of course, the tubes now known by the names of the ducts of Malpighi, of Gœrner, &c.

according to him, do not communicate by any direct orifice with the urethra; and thus one error led to another, and the misrepresenting the exact structure of the female organs produced a corresponding misrepresentation of those of the male. A physiological system of the growth of the fœtus flowed from all this, of an almost unparaleled absurdity; the female seminal fluids were supposed by him to distil through these tubes into the solid wall of the uterus, and there, coming in contact with the male fluids, engendered the human being. I will not comment farther upon these doctrines, fully aware that, if possible, greater errors have been committed since his day, by physiologists at least as celebrated as Thomas Wharton.

But we need not attempt to refute these doctrines by reasoning or theorising: a single fact, against which no argument can be of any avail, informs us that the fallopian tubes and vasa deferentia are found constantly together in the females of certain animals; their analogy may, for argument sake, be admitted, but I presume no one will venture to call them identical, or imagine them to be formed out of exactly the same parts.

I need not at present dwell on the precise nature of the clitoris, inasmuch as we shall discuss the matter more fully in the second part of the memoir. Laurenti called it the female penis, and to doubt its close analogy in all points with the corresponding structure in the male would be to doubt the evidence of sense. I should be sorry to bring before this Society all that has been said by anatomists and physiologists regarding its uses or functions, and its abuses: as they mistook its nature, and the reason of its being present, it could hardly be expected that they should speak rationally about it. It is a male organ, forming no part of the female economy. Not unfrequently the same organ in the male, by an accidental, though original malformation, comes to resemble almost in all respects the female clitoris. The reverse of this, together with the probable cause of its size in the yellow races of Africa, the accidental extension of the urethra through it in certain quadrumanous animals, shall be considered fully in the second part of this memoir: the opinions offered regarding its uses,

and the cause of its presence, by modern physiologists, are too mean for criticism; for it will be found that they have not advanced a step since the days of Wharton, who thought that this organ, together with the greater labia, were formed "*partem ad tutelam partium internarum, partem ad titillationem in coitu.*"

The fullest account, so far as I have been able to collect, which has been given by any of the older anatomists, as well of the structure known to them as of the theories supported by anatomists, whether contemporary or prior to his age, is given by Bauhin, whose works were published in 1621. That he stole much from Vesalius, as was the practice of all the anatomists of his time, must be admitted; but independent of this, he was obviously a very learned man, and occasionally observed for himself. In his accounts of the female parts connected with generation, he destroys all pretension for originality on the part of modern theorists as to the generative organs, and his language is so clear that it is difficult to imagine what outlets the recent promulgators of these doctrines will be able to discover in order to avoid the charge of direct plagiarism. The heading of Chap. 33 of *Theatrum Anatomicum* is as follows. Galen hath shewn us (*De usu partium*) that all the parts of men are found in women; they differ merely in position; for Galen was of opinion that a woman had all the parts that a man naturally has perchance, because as woman is first born a man (*cum femina homo nata sit*, page 111)—[many of the moderns have exactly reversed this doctrine, and with a greater show of reason, since the principal male generative organs are situated internally]—whatever parts are found in him ought to exist in her, and they differ only in this, that in women these parts are hid internally (*Hæc intus sunt conditæ*), but in men are situated externally towards the perineum; and he adds, moreover, a comparison implying that they understood and had pushed analyses as far as any modern—I mean as regards the general type of all animals. He adds, *Quod etiam intalparum ocnlis accedit*. From this phrase one might suppose that they considered the female organs as rudimentary male organs, differing in situation as differing in strength of develop-

ment. I have heard the theory of Galen brought forward as a novelty, and taught in the Continental schools in 1821, with no modification, and almost in the same words; and indeed it will be found to be the basis of almost every modern theory of the generative organs, as I shall afterwards prove in the second part of this memoir.

When we carefully examine these anatomical works of Caspar Bauhin, it is quite obvious that physiological theories, or prejudices, for they do not merit much the name of theories, led to false views of structure; the observation of facts was forced to yield to hypothesis. This hypothesis of the exact analogy, or, I should rather say, identity, of the male and female parts—and so preoccupied were they with these doctrines that they even called the round ligaments, cremasters (they traced them to the knee)—flowed from a preconceived theory of the female seminal fluid, and was founded on it. Hence their names of testes muliebres, applied to the ovaria, and vasa deferentia applied to the fallopian tubes. When we read this page of Bauhin's works from which I now quote, one might almost imagine they were perusing a portion of a modern continental work. He compares the uterus to the scrotum—"Uterus vero scroto virili a Galeno assimilatur quasi scrotum uterus sit inversus ab ossibus pubis propendens; et sic scrotum et uterum solo situ ab inversione distare censet." He goes on to state, "and thus if you imagine the inverted scrotum to be thrust as it were betwixt the urinary bladder and rectum, what was formerly scrotum may now be termed uterus—(quod antea scrotum erat nunc uteri rationem obtinebit.)" He next compares the vagina to the penis, and seems to consider all these organs as essentially the same. "Uteri vero collum loco penis erit, cum collum et penis idem sint longitudine fritione et refriktione ab iisdem in eundem ductum semen effundetur." He admits, however, that they differ in situation, as being internal in women, external in man; which distinction as to situation was, so far as I remember in the modern discourse I have heard on this subject, nearly the only difference allowed to exist between organs whose actual functions are diametrically op-

posed to each other. But these, he says, are mostly Galen's notions, whereas he himself would rather compare the vagina to the neck of the scrotum: (Collum uteri collo scroti respondere, et peni virili, penem muliebrem quem clitoridem vocunt.) Fallopius, following in the same field of observation, had other views; for inasmuch as the highest problem which can possibly be solved by the human mind is the theory of generation, the most mysterious of all vital processes, so the organ, or immediate instruments by which a living being may be called into existence has naturally at all times deeply engaged the attention of the philosophic world. Fallopius, whose anatomical discoveries well entitled him to theorise, compared the female uterus to the male penis, the body of the uterus to the glans, the vagina to the body of the penis, assigning as a reason, "Natura masculos similiter ac fœminas iisdem organis præditos esse voluerit, ut sibi penitus similes generare possint." To the male and female fœtus he assigns, in their embryo state, the same parts, (eodem membra): and whether the fœtus were to prove male or female depended on the greater or less degree of heat, (pro majore vel minore calore): and so when by the great force of heat, these parts protruded, the fœtus proved male, but by the deficiency in the heat the parts remained within the body, enclosed, as it were, in the trunk, the child proved female. I greatly wonder how so sensible a man as Fallopius could forget in his theory the obvious resemblance, almost identity, of structure, situation, blood-vessels, connexions, that exist between the clitoris and penis, allowing his views to be perverted and twisted by false views of the animal œconomy. He mistook, also, the circulation of the blood, though he discovered the valves of the veins, and knew all the facts regarding it, and so missed an immortal fame. I think his notions about the less degree of heat in females and female parts is not supported by modern experience. The most modern doctrine, and that most extensively admitted, teaches that all embryos are female. These doctrines, then, tacitly avow the male to be a more perfect animal, inasmuch as the non-development of male organs would leave the embryo of its original female sex. The ancients said that

this was effected by the greater heat, and this is the only difference I can discover between the doctrines of Galen and the ancient anatomists, and the more cautiously expressed theories of Meckel and of other modern physiologists. But in speaking of the older anatomists I ought not to include all, for amongst them there were obviously men such as Laurentius, who, possessing either less genius or imaginative powers, asserted the genital organs of both sexes to differ greatly from each other both in situation, and structure, and number.

On this supposed want of heat in the female the older anatomists explained everything: they had laid down a principle which, right or wrong, like the modern doctrine of "formations arrêtées," they applied on all occasions. This want of heat, this coldness of females, explained why the ovaria remained within the body, and were smaller; why they have no epididymis; why the prostate scarcely exists in females; why the spermatic blood-vessels are shorter, &c.

It must be admitted that Bartholin's notions of the presence of male organs in female structure must have been somewhat more rational than certain of his contemporaries. He speaks of a prostate in women, but did not mistake the uterus for it, as Meckel has done: he looked for it where, without doubt, he would have found it, had it existed, namely, betwixt the female urethra and anterior surface of the vagina.

But I perceive that the discussing these points further in this part of the memoir will lead directly to the nature and causes of hermaphroditism, the theories regarding which I propose discussing in the second part of this essay: enough has been said here to show that in discussing the modern doctrines of hermaphroditism we shall not be considering novelties, but rather opinions coeval with the earliest period of philosophical anatomy.

Having shewn, in the first section of this memoir, that there may exist in females of any animal, organs which in their character are essentially male, though they be not called to perform any particular function, but are present simply, as shall be more fully explained, by a law affecting the type of the

generative organs, let us now consider this subject more in its details, and endeavour to determine, in as far as we can, if any organs essentially of a female character exist in the male structure, and thus lay the foundation for a rational physiology of these organs, and which shall explain why they are present, and how they may be absent, without any reference whatever to the doctrine of final causes, general analogy of living beings, imperfect development of parts, or to any other doctrine, physical or metaphysical, which has been proposed. That such an inquiry is necessary, no one who is acquainted with the reasons assigned by physiologists for the presence of certain organs in the males and females of animals, will venture to doubt; neither will any one who has reflected on the uses assigned by almost all physiologists and anatomists to these organs; sporting opinions regarding structure, which, without employing a harsher style of criticism, may be declared to be too mean for notice. The most approved modern works consider the clitoris as an organ almost exclusively calculated for pleasure, which, together with most other opinions regarding the uses of organs contained in most modern physiological works, I feel inclined to consider as inferior in rationality to the notions of Riollan about the uses of the rudimentary mammæ upon the male breast, his opinion being that they were placed there that woman might not boast of the superb organs which nature had bestowed upon her*.

* The highly philosophical McCullagh has remarked that in explaining the phenomena of nature, the rabble fly at once to final causes. But so do the Oxford philosophers and geologists. A curious but not singular instance of the accuracy of Dr. McCullagh's remark, I met with in travelling between Biggar and Edinburgh, which it may not be out of place to relate. The driver of the chaise, also its proprietor, in which I travelled, asked my permission to give a ride for a few miles to a very decent-looking woman, who seemed, and in fact turned out to be, the wife of a small tradesman, but in good circumstances. The lady was garrulous, and my driver (a married man) inquisitive: she soon entered on her family history, during which we learned that although she had been married for about four years, she had not yet been blessed or cursed with any family; but what was more extraordinary, she had a brother, to whom nature had denied all vestige of the male organs. And on my driver asking what she thought might be the cause of so strange an occurrence, she replied unhesitatingly, that it was clearly an interposition of a special providence, in order that somebody might be left at home to look after their aged mother!

In our endeavours to determine the organs which are essentially male, which in fact constitute the sex in him, the first place in importance must assuredly be assigned to the testes, which have nothing strictly analogous to them in the female: some, indeed, have ventured to say that the ovaries are the analogous organs to the testes, and some have even gone farther, and asserted that originally in the embryo there exist but one organ, and one tube leading from it, and these are convertible into either testis or ovary, and vas deferens or fallopian tube, according to the determination of the sex; and this opinion, which at the present moment seems to prevail with almost all the great anatomists of the present day, is of vast antiquity, and yet there is no foundation for it, but the most positive and direct proofs of the contrary drawn from anatomy and physiology; proofs which, I trust, when fully submitted to the society, will readily convince every one that the testes never yet under any circumstances were changed into ovaries, nor the vasa deferentia into fallopian tubes. To proceed, then, with the determination of the organs, we shall consider the testes and vasa deferentia, vesiculæ seminales, and prostate gland, as essentially male, as having nothing at all analogous to them in the female naturally; and therefore if all, or any part, be found to exist in her, it must be considered as the remains of the male structure, in no shape necessary for the performance of her functions, but accidentally present from circumstances which shall be more fully explained hereafter. In man, moreover, we have, in addition to these structures, all that portion of the urethra which is anterior to the membranous part, which, together with the penis or corpus cavernosum, and corpus vasculosum urethrae, are parts exclusively male wherever found, whether in male or female, that portion of the urethra which is behind the membranous part leading to the bladder being common to the male and female. Now I may mention, though in a dogmatic way, reserving the proofs till I come to speak of the female organs, that we find nothing analogous to the seminal vesicles, prostate gland, or ductus ejaculatorii, in the female of most animals, and when we do find

them, as no doubt in certain female animals a part of these would seem to exist, we are warranted in considering them male organs accidentally present. Now, in addition to these, we find, moreover, in the male of many animals, certain organs which are unequivocally female; such are the mammae, which are placed on the human breast: the history of these organs, and the physiology assigned to them, is an exceedingly curious subject; large in some males, small in others; they have been known even to secrete a fluid. They contain milk in most very young children. Wherever found they are essentially female organs. Anatomists have been anxious at all times, and in all ages, to point out in male and female what they considered analogous organs, and accordingly the rudimentary mammae on the male breast could hardly escape their notice; they seem indeed, to have considered them as essential to male structure, inasmuch as we find them devising reasons for their presence, ascribing it to analogy, which, if it imply anything, implies a theory, or assigning to them more positive uses, such as that of ornamenting the breast, cherishing the heart, and keeping it warm, and other prodigious absurdities of this kind. Riolan's notion after all is perhaps the best: "*ne mulier superbum animal gloriaretur se mamas habere, quas natura viris denegasset.*" — Anthrop. lib. 2, 3, p. 208.

Previous to birth the testes are lodged in the abdominal cavity: now we find leading from them to the scrotum, a whitish fibrous-looking cord, to which Mr. Hunter gave the name, and assigned the duties, of a gubernaculum, or a regulator of the testes. I have often thought this structure might be the remains of a female organ, viz. a portion of the round ligament; the female apparatus not having at this early period of the growth of the fœtus entirely disappeared. M. Carns considers the round ligaments as analogous to the gubernaculum. But I throw out this as a mere conjecture or theory, and not by any means as having been confirmed by actual dissection. The cremaster is a male organ; in those cases in the human structure in which the testes does not descend into the scrotum, and which we know sometimes to be the case, in cases in which

they are obviously imperfectly developed, we find that then there is no cremaster present, or at the most a single fasciculus or two of pale muscular fibres: thus, then, the descent of the testes into the scrotum in these animals in whom by a law of their nature they ought to descend, is somehow or other connected with the presence of the cremaster: if the organ does not appear in its proper place, the cremaster does not seem to form, but these effects may be concomitant, merely the general result of a common cause acting on, and influencing both. In one case examined by me, of a person about thirty years of age, the testis of the right side had not descended; from it there proceeded downwards into the pelvis a vas deferens seemingly well formed, whose course was to the fundus of the bladder, where we found two vesiculæ seminales equal in bulk to each other, and a prostate gland of the usual size: as the vas deferens of the right side was crossing the brim of the pelvis there proceeded upwards towards the deep inguinal ring, following that course which the vas deferens usually takes, a cord seemingly composed of cellular fibres, together with a few blood-vessels. A thin cord proceeded outwards, passing by the deep ring into the inguinal canal, following the course of that canal as far as the external abdominal aperture, and was there lost in the surrounding cellular membrane: a few pale delicate looking muscular fibres were found in the inguinal canal, following the usual course of the cremaster. Notwithstanding what has been said of the rudiment of cremaster muscle in females, I consider this muscular apparatus as being distinctly male; and even were it proved to be present in all females, which is not the case, this would in no shape alter my opinion; neither do I consider the prostate gland or seminal vesicles as having any representative or analogous structure amongst the female parts. With the exception of Bartolini's views as to the nature of the mucous glands placed betwixt the superior surface of the vagina and urinary bladder, no one has pretended even to shew any structure resembling the prostate in the female, and if the seminal vesicles do exist, as they are known to do, though in a rudimentary state, in

some female pachydermatous and ruminating animals, they are, as we shall afterwards shew, rudimentary male organs, existing in the female. The penis is strictly a male organ, though found in a rudimentary state in all women, I presume, and in the females of most animals: though in most males it serve the purpose of a canal for the discharge of urine, it is yet in some animals seemingly exclusively intended as a generative organ, performing one function only. I consider, then, the organ as exclusively generative in this sense in all male animals in whom it is present, and include therefore all that portion of the urethra and its corpus spongiosum extending from the bulb to the glans inclusive. A deficiency in any portion of the canal is generally said to be an approach to hermaphroditism: it certainly indicates a deficiency in the development of the male organs. The doctrine then is this: the organs I have designated to be male are essentially male organs wherever found; they do not, when transferred to the other sex, take on the action of other organs, they perform no specific function there, nor are changed into any other structure, and thus called on to perform other functions if transferred to the other sex, as they sometimes undoubtedly are: we never find them converted into other organs; the testes will never become ovaries, notwithstanding the assertion of many eminent anatomists of ancient and modern times, nor are the vasa deferentia convertible into fallopian tubes, seeing that they co-exist in females of the ruminating and pachydermatous animals.

When male organs, therefore, are found in females, they shew an approach to hermaphroditism in the individual, trivial and ineffectual if the organs present be merely in sections or in parts, and still more so if they happen to be unimportant organs; but singular in the result, should the organs present happen to be the testes, the animal may then be found to rise through the various shades of double sex to hermaphroditism nearly if not complete.

REMARKS
ON THE
IMPUNITY OF CERTAIN ATTEMPTS
TO MURDER,
AND THE GROUNDS OF THAT IMPUNITY.

To the Editor of the Medical Gazette.

SIR,

The following remarks were in great part drawn up with a view to a future edition of a work published by me in 1838, entitled "Elements of the Pathology of the Human Mind," of which they might form a chapter. I should not have thought them worthy of being laid before the public in their isolated form, but for the peculiar circumstances of the practical question to which they relate. An intention has been expressed by the highest legal authority in Great Britain to review this important subject, and to frame, if it seem good to him, some legislative measure in relation to it. It appears reasonable that all possible data should be accumulated for such a consideration; and, under this impression, I have thought it not inexpedient to offer to you this contribution, when, however small its importance, it may be of most use.—I am, sir,

Your obedient servant,

THOMAS MAYO.

56, Wimpole Street,
Nov. 15, 1843.

"A child is born in the garrets of St. Giles's, the offspring of a prostitute and a thief. He receives a suitable education, and he adopts his father's profession. After following it with assiduity and success, he is arrested in the course of it, and tried for his life. His early habits are ascertained on unquestionable evidence; but do these considerations soften the rigour of the law, by placing him before the public as an irresponsible being, the creature of circumstances over which he had no control? By no means; in one respect they tend to insure his condemnation, namely, in making his deliberate performance of the criminal act more probable. Finally, this person is hanged or transported, according to the nature of his offence. And it is probably very fit that he should be so treated. I do not object to the decision of the law in the case which I am supposing, provided a consistent view

is taken of certain other cases in relation to the plea of irresponsibility*."

It is clear that we do not test the liability to punishment of the above offender by his presumed moral responsibility, but by some other criterion; and this criterion I will at once assume is furnished by the question, whether punishment in the supposed case will, or will not, prevent a repetition of the offence?

Now, the above remarks have an important bearing on the subject of mental unsoundness, viewed in its relation to delinquency. Certainly the burthen of proof rests with him who impugns the position, that the same criterion should be applied to the acts of a maniacal offender; so that the exculpation founded on presumed irresponsibility, which is denied to the sound in mind, should be equally denied to the unsound. I will therefore at present assume, that the liability to punishment of both parties must be determined in reference to the question, whether punishment will prevent a repetition of the offence? Those who would deal with the unsound in mind, irrespectively of this criterion, as being irresponsible agents, must, in parity of reasoning, exculpate and set at large the thief or murderer, whom we have above described.

In truth, the tendency which has unconsciously operated on the public mind to disregard the community of principle on which the sane and the insane may, in many respects, be dealt with, had largely contributed to that moral mismanagement of the insane, which many wise and humane persons are, in the present day, carefully endeavouring to obviate in the regulation of establishments for their relief. The mental affections under which they are labouring do not prevent their being influenced in a high degree by a sense of right, by fear of consequences, by gratitude, and by a well-modified love of praise.

It is perhaps needless to say, that the prevention alluded to in this inquiry is general, not particular: in other words, that it is applicable to all members of the community, and not peculiarly or principally to the delinquent punished.

* The above passage constituted part of an article contributed by the author to the first number of the *London Review*, formerly edited by the Rev. Blanco White.

What, then, are those states of the unsound in mind, for which, and under which, they must be held unamenable to punishment for offences against society, on the ground that their punishment will not prevent the occurrence of a similar offence?

We are informed by the highest authority of the land, the Lord Chancellor, that the actual law, in reference to the greatest offence, the crime of murder, is that pronounced by Judge Leblanc. "It is for you to determine," says Mr. Leblanc to the jury, in a case of attempt at murder, "whether the prisoner, when he committed the offence with which he stands charged, was or was not capable of distinguishing right from wrong? whether he was under an illusion with respect to the prosecutor, which rendered his mind insensible of the nature of the act he was about to commit, since in that case he will not be legally responsible for his conduct? On the other hand, provided you shall be of opinion that when he committed the offence he was capable of distinguishing right from wrong, and not under such an illusion as disabled him from distinguishing that he was doing a wrong act, he would be answerable to the justice of his country, and guilty in the eye of the law." Such, no doubt, as sanctioned by the Lord Chancellor, with reference to the opinion also of other judges, is the law of the land. The utter vagueness of the criterion, "knowing right from wrong," has been exposed by able writers, and by none more ably than the author of an article on the trial of Macnaghten, in the 77th number of the Westminster Review; though perhaps that author somewhat magnifies the absurdities to which it might have been presumed to lead, in parity of reasoning, such as exculpating Guy Faux and Ravailiac; for he overlooks the fact, that the ignorance which is regarded as exculpatory, is presumed to be the result of a maniacal delusion. Yet, modified in this way, it is still a perilous doctrine, which regards ignorance of right and wrong a ground of impunity. If justice be the plea on which such ignorance is to confer such exemption, the supposed case with which I have commenced this essay stands full in the way, as it would claim, by parity of reasoning, equal exemption;—if it

be presumed that punishments inflicted under these circumstances will be non-preventive, we are met by the fact, that the insane are largely subject to influence from fear.

The expressions by which the present Lord Chancellor, in the case of *Rex v. Offord*, seemed disposed to construe that ignorance of right and wrong which should privilege the insane delinquent, afford a definite and intelligible modification of the above criterion. The expressions to which I advert, as used by Lord Lyndhurst, were adduced by the Attorney-General in the prosecution of Macnaghten; and it is perhaps to be regretted that they did not receive further enforcement from him, and from the learned judge before whom the cause was tried. The whole passage we give in the Appendix. (See No. 1, p. 304.) I would call my reader's attention to that part in which his lordship recommends that the plea of mental unsoundness should not avail, if the prisoner knew, at the time when he committed the act, what its effect would be in reference to the crime of murder. Now the converse of this proposition, that such ignorance, namely, as is there supposed of the act in reference to law, ought to avail as exculpatory of a delinquent under a plea of insanity, constitutes, I believe, a ground of considerable space, and adequate to contain a large proportion of the cases requiring such exculpation. The punishment of an insane person, whose insanity has proceeded to this point, can in no degree answer the intention of punishment. It cannot prevent a repetition of the offence, for it will not be appreciated by the persons whom it is supposed to influence. Meanwhile, this description will embrace all the mass of cases which fall under the name of delirium; cases well recognised, indeed, in practice, but not easily fixed by definition. Again, it will embrace all such acts as, springing out of an insane delusion, would be justifiable if that delusive impression were founded in reality. Thus a person insanely imagining his own life the object of a conspiracy, and killing another person, under circumstances which the law would warrant as constituting an act of self-defence, if the conspiracy were real, would be protected by the above plea against penal

consequences. The prior delusion of the offender involves, in this instance, an ignorance of the criminal nature of the act. We will put this case thus: A. considers himself the object of a conspiracy, and B. one of the conspirators. He meets B. in a solitary place by night: his fears are roused under influence of his delusion, and he puts B. to death in presumed self-defence.

In these cases, it will be observed, there is a presumed state of mental unsoundness in relation to the offence at the moment of its commission. Now this is, in truth, the principle embodied in the expressions of Lord Lyndhurst, to which I have alluded; protective, indeed, of the interests both of the public and of the insane offender. He whose insanity incapacitates him from recognising the nature of his offence, in reference to the laws of his country, is under the immediate pressure of that state in relation to that offence. The punishment of acts not merely resulting from, but performed under insanity, *i. e.* under false perceptions or delirium, will in no case constitute a preventive example.

If I am asked why I limit the impunity conferred by insanity to actions performed under its presence, and do not extend it to actions springing out of insanity, I answer, it is quite certain, in the first case, that the agent has no control over himself; and this complete certainty would make his punishment unpreventive: in the other case, no such certainty exists, and we habitually deal with classes of offenders who appear even more unable to control themselves, as if they *were* possessed of self-control; and we find such punishments preventive of crime, and protective of society.

The distinction which I am endeavouring to illustrate, with a view to judicial proceedings, is one habitually carried out in the management of the insane. Every experienced manager of an establishment knows, in most cases, when his patient is actuated immediately by the disease, and when his mind is proceeding normally. He occasions the patient to regulate, in some degree, his own aberrations by the use of his reason.

It is, however, conceivable that the insane person, whose delinquency is in question, may not be obviously unaware of the fact, that the act which he is preparing to commit is contrary

to the law of the land; he may comprehend its nature in relation to law, yet still, in applying the great principle to which this consideration is subservient, we may be compelled to admit that the offender, in the case supposed, is not a legitimate and fit object of punishment; that he is not one whose act the threat of punishment could have prevented in *him*, or the example of whose punishment could deter others similarly situated. Such is oftentimes, in respect to the offence, the unhappy parent, whom a morbid impression impels to murder; who asks, perhaps, to be manacled and confined, lest she should obey this impulse, and slay her beloved child. (See Appendix, No. 2, p. 304.) Again, the attached and faithful subject and soldier, who is led by an irresistible impulse to shoot at his commander and sovereign. In these cases, as in that previously considered, in which the offender is presumed ignorant of the nature of his act in reference to law, there is a mental impression, pathologically of an insane kind, and also placed beside or beyond any influence from threatened or prospective punishment. Hadfield himself apparently shot at the king *with a view to being capitally punished for it*.

In cases such as these, the insane state not only has led to the delinquency, but also, pervading the whole character of the delinquent, has abolished for the time those principles which, in a normal state, would offer resistance to an illegal act, whether suggested by a real cause or by a delusion; thus making death by the hand of an executioner, in the one case, and the murder of a beloved child, in the other, an object of desire.

But eminent authors, such as M. Georget and Dr. Prichard, are of opinion that the plea of insanity may comprehend that class of persons who are termed monomaniacs, so as to render *them* also irresponsible*, or unfit

* I entirely assent to Dr. Prichard's opinion, that perfect soundness in other points is not compatible with the presence of monomania. But I do not imagine that the law either does contemplate, or ought to contemplate, this as conferring general irresponsibility. In truth, the extent of eccentricity which may render the subject of it deserving of medical attention and management, does not necessarily exclude that degree of self-control which the fear of punishment calls into action. Surely the public interest requires that a person should be amenable to penal law for those aberrations for which he could not be confined or coerced as insane, without an infringement of his just rights.

subjects for punishment. "The conclusion which M. Georget arrives at," says Dr. Prichard, who agrees with him, "is as follows:—Partial insanity, or monomania, excludes the idea of culpability or criminality, and takes away from the affected person all responsibility for his actions, whatever may be the extent or nature of the delusion under which he may labour."

We must apply to the opinions of these gentlemen the criteria above adverted to, namely, the question of justice, and the question of preventiveness of punishment as inflicted for the supposed delinquency. The irresponsibility of the monomaniac on the first of these grounds, that of justice, is disposed of by the precedent with which our essay has commenced. The person who can reason upon his crime, who can devise systematic means for accomplishing it, who can form and weigh opinions respecting his chances of escape, who can conduct the ordinary business of life, can take care of his property, that man cannot, consistently with justice, be made less responsible morally for his actions, than the unhappy offspring of the prostitute and thief, whom we there supposed. With respect to the other criterion, the question, namely, whether his punishment (the punishment of the monomaniac) will be preventive, the burthen of disproof must rest with those who venture to undertake a denial of this supposition.

Let us now consider, in relation to these principles, and in illustration of them, the important case which has given occasion to the public anxiety on the whole subject; I mean the case of Macnaghten. In the first place, no proof was offered, or, I presume, could have been offered, that he was not cognizant of the nature of his act, in reference to the laws. Neither, allowing him the benefit of a pre-existent delusion, could he have construed the circumstances under which he performed the fatal act as affording grounds for it on the plea of self-defence under an immediate attack. These grounds excluded, what other grounds were there for supposing that his punishment might not deter similar offenders, or that the apprehension of punishment would not have deterred him? Was his insanity, in relation to the act committed, analogous to that of Hadfield, or the infanticide mother?

Did it subvert or run counter to the ordinary workings of the human mind, or was it not rather in strict unison with them? If, as I believe to have been the case, he was a monomaniac, if he had one set of morbid associations of thought, he was not therefore, *primâ facie*, incapable of learning, or of teaching others, by the example of his punishment, that a strong desire of vengeance, or, if you please, of prevention of mischief, must not be gratified in defiance to the laws of the country. To say that he was incapable of making these distinctions would be to assign to him a pathological state of which no evidence was adduced. He must have been a maniac, not a monomaniac.

APPENDIX.

1. In this case the prisoner was indicted for the attempt to murder a person of the name of Chisnall, by shooting him with a gun. It appeared that the prisoner laboured under a notion that the inhabitants of Hadleigh, and particularly Chisnall, the deceased, were continually issuing warrants against him for the privation of his liberty and life. Several medical witnesses deposed to their belief that, from the evidence which they heard, the prisoner laboured under that species of insanity called monomania, and that he committed the act while labouring under the influence of this disorder. Lord Lyndhurst, who tried the cause, in summing up told the jury, that "they must be satisfied, before they could acquit the prisoner, *that he did not know, when he committed the act, what its effect, if fatal, would be with reference to the crime of murder.*" The question was, did he know that he was committing an offence against the laws of God and nature?" The expression in italics I presume to accept as Lord Lyndhurst's practical application of the latter question, which is another expression of the vague criterion of our law, the knowing right from wrong.

2. We might refer our readers to a case recorded in Rivington's Annual Register for 1822, p. 97, as a painfully good specimen of this form of insanity. A young married woman comes into a neighbour's house at 11 o'clock in the morning, and in a delirious manner,

* *Times* newspaper—Trial of Macnaghten.

with wild gesticulations, asserts that she has cut off her child's head, in order that she may be hanged. She had previously been in good health. For this act she is tried, and very properly acquitted, on the plea of insanity. It appeared that she was perfectly sober, had had no quarrel or difference with her family, was an affectionate mother, and was at the time anxiously trying to nurse this child, to the detriment of her own strength.

This most strange form of aberration seems in many instances connected with a perverse habit, which education might possibly do something to prevent. All must be conscious of a defect of mind, which, in some *sane* persons, exists in a very high degree, and which may form the starting point of an aberration, namely, the strong nervous inclination to perform some act which the agent at the same moment regards with the deepest horror: to jump down from a precipice, &c. This *small* insanity is not undeserving of attention in early life, if only for the sake of more important forms of the morbid tendency, to which it may lead.

[To be continued.]

DIGITALIS IN EPILEPSY.

To the Editor of the Medical Gazette.

SIR,

IN the work published by me in 1841, in which I detailed some cases illustrative of the efficacy of digitalis in large doses in idiopathic epilepsy, I incidentally hinted that probably in mania, and more especially when complicated with the former disease, the same medicine administered in the same way would be found to exercise a very decided influence. To this opinion I was led principally by a very striking case, related at page 23 of that work, in which a perfect cure of the two-fold disease followed the administration of the heroic dose during a maniacal paroxysm. Having lately met with several cases strongly confirmatory of the correctness of this view, shewing likewise the safety of this medicine in doses much larger than those usually given, I am induced to present them to the profession.

CASE I.—A young woman, æt. 27, in whom epilepsy had existed from an early childhood in the idiopathic form,

836.—XXXIII.

was frequently attacked by mania after the fits, and in some instances mania took the place of the primary disease. The fits were generally preceded by an aura; premonitory sensations being felt sometimes for days previous. After enjoying an unusually long respite, she was attacked by mania on the third of October. She remained sleepless for three days and nights, and talked incessantly. Her bowels were open; her pulse above 100. She had taken neither food nor drink for the three days. I gave her on the third day ʒij. of Tinct. Digital. prepared from the fresh leaf. On that night she slept soundly, awoke composed, and made a hearty breakfast. Her pulse continued regular, of good strength (108). On the next day her pulse was 100, and she was more tranquil. In a day or two she recovered her wonted serenity.

The next case occurred in the general hospital here, and I am indebted to the kindness of my friend, Dr. Jones, for the opportunity of trying the remedy.

CASE II.—A man, æt. 60, a musician, seven years epileptic. Cause not assigned; disease not hereditary; temperate; no previous treatment.

Present state.—August 20, 1843.—His fits occur at uncertain intervals; is seldom more than three days free; has sometimes several in one day. Fits are generally preceded by flightiness of manner. Is more liable to them when constipated. Was at first subject to violent headache, not so at present. Maniacal fits, so violent as to require restraint, frequently alternate with the epileptic. Memory impaired; enunciation embarrassed; attacks sometimes accompanied by a cordiness of temporal arteries, and a tightness and fulness felt in the head.

Sumat. ʒj. Tr. Digital. ter in die.

23d.—Tr. Dig. omitted on 22d, on account of constipation; resumed to-day; pulse 88.

25th.—Smart vomiting; bowels slightly affected; pulse 64, regular.

Omit. Digit.

26th.—Had two fits this morning.

28th.—Violent delirium; bowels open.

Sum. stat. Tr. Digital. ʒij.

Pulse being 92, small and soft; but temporal arteries developed; face and

head warm and perspiring. In four hours he was quieter; pulse 96, and took 5j. Tr. Dig.

29th.—Tranquil; slept well; skin perspirable; no vomiting; bowels confined; pulse 80.

30th.—Smart vomiting yesterday; bowels opened by purgative medicine. Is rational; pulse 96.

Sept. 2d.—Maniacal fit last night, for which restraint was used. Had an epileptic fit this morning. Is now quiet and rational; pulse 96; bowels free.

3d.—Another maniacal attack last night; tranquil at present, though not quite collected; pulse 80.

6th.—Being rather excited this night, and pulse 92, had Tr. Digit. 5ij.

7th.—Maniacal tendency still continues; pulse 84; no vomiting.

St. statim. Tr. Digit. 5ij.

8th.—Tranquil; pulse regular; slept.

9th.—Tranquil; pulse 84, regular.

10th.—Maniacal tendency; pulse 96.

St. stat. Tr. Digit. 5ij.

11th.—Slept well; after a hearty breakfast had a severe fit of vomiting; pulse 96, regular.

12th.—Pulse 84, slightly irregular; vomited again.

13th.—Tranquil; marked intermission of pulse.

14th.—Tranquil; intermission less; pulse 74 to 84.

17th.—Maniacal tendency; pulse 84, regular, and rather cordy.

St. statim. Tr. Digit. 5ij.

18th.—Quiet night; pulse 92, slightly irregular, but not intermitting. No vomiting.

21st.—Pulse 84, with very marked intermission.

23d.—Look wild; pulse 102; bowels constipated.

Statum. Pil. Purg.

24th.—Bowels open; tranquil; pulse 76, still intermittent.

25th.—A severe fit at half-past 4 A.M.

Sumat. stat. Tinct. Digit. 5ss.

9 A.M.—Pulse 72. Half-past 5 P.M.—Qualmish, but no vomiting; pulse 61 to 64, intermittent.

26th.—Vomited a great deal in night. Is now (half-past 9 A.M.) sleeping. Pulse 60, regular; slight hiccup.

27th.—Tranquil. Vomiting stopped; bowels confined; pulse 88 to 92.

Pil. Purg.

28th.—Tranquil, but weak; pulse 78 to 80, cordy.

29th.—Pulse irregular still.

Oct. 2d.—Pulse 90, regular.

3d.—Talkative in night; manner excited; pulse 90, regular.

5th.—Has had six fits since last report; pulse 92, regular. Is rational.

Sumat. statim. Tr. Dig. 3iv. ($\frac{1}{2}$ -past 9, A.M.)

6th.—Vomited a little; pulse 108, regular; rather stupid, but rational.

7th.—Is quiet. Pulse 64, intermittent.

9th.—In the night of 7th, being rather excited, got Tr. Dig. 5ij. Quiet since. Pulse 98, slightly irregular.

Had a fit on 11th.

Between this date and the 3d inst. he took six draughts of Tr. Digit. of ij. each, and had no fit.

From 24th to 26th Oct. he was delirious, constantly catching at imaginary objects in the air; but was tranquilized by two draughts containing 5ij. of the Tinct.

I have detailed this case at considerable length, and would remark, that both cases tend to show (as I have already endeavoured to prove in my essay) that, when digitalis is administered in sufficiently large doses, the stage of excitement becomes, as it were, evanescent, and the medicine acts, to all intents and purposes, as a direct sedative, and this even in cases where a confined state of bowels exists; contrary to the opinion of Dr. Halloran, who asserts that in this case it is a stimulant. It is, no doubt, desirable, but *not indispensable*, that they should be open; which it is well to know, in those cases where, in order to avoid the sad alternative of coercion, speedy relief is necessary, and where time could not be afforded for the operation of a purgative. I cannot but express the hope that physicians of lunatic asylums, and other establishments presenting extensive opportunities of testing these views, may be induced to do so, as it would be an inestimable boon conferred on the unhappy class of beings to whose relief they minister, if any so easy means should prove a safe and efficacious substitute for circular swings and strait-jackets. Dr. Holland, in his Medical Notes and Reflections, states his opinion, "that one cause of the frequent failure of digitalis is its too timid administration;" and I must

say, that from these, as well as from many other cases which have come under my observation, I am more and more confirmed in the opinion which I formerly advanced, that epilepsy and epileptic mania, in obedience, it would seem, to a general law of disease, confer a tolerance of an appropriate remedy in doses which would be dangerous under other circumstances; and, in cases where the heroic dose is inadmissible, admit frequently of palliation by the administration of digitalis in doses hitherto little dreamed of in practice. It is quite certain that in the second case here recorded the digitalis repeatedly, and with certainty, controlled the maniacal tendency, which, in this case, was generally attended by more or less vascular excitement; while in the first case, in which no such concomitant symptom was found, its action seemed no less prompt and beneficial. It is likewise worthy of note, that the characteristic effects of the medicine on the circulation seemed to follow its sedative effect at an interval of 24 or 48 hours.

The subject of the second case has been taking regularly, since the 8th inst. Tr. Digital.—Spt. Tereb. aa. ʒj. morning and evening. His pulse to-day is 72, and regular. He continues perfectly tranquil.—I am, sir,

Your obedient servant,

EDMUND SHARKEY, M.D.

1, Winchester Place, St. Helier's, Jersey.

FIBRINOUS DIARRHŒA,
OR
DIARRHŒA TUBULARIS OF
DR. GOOD.

By JOHN GRANTHAM.

(For the *London Medical Gazette*.)

THIS disease is of rare occurrence, and of a most unmanageable kind, assuming, in the generality of cases, a chronic character. Dr. Golding Bird, in the Guy's Hospital Reports, says, "It is probable that the follicles are the principal seat of the disease; for we know that they sometimes secrete a dense mucus, differing little in its physical qualities from coagulated albumen, or even fibrin; and the researches of modern chemistry go far towards shewing, not only the close connection, if not identity, between fibrin

and albumen, but also that the formation of mucus requires little more than the addition of saline matter to albumen in a state of minute subdivision; and conversely, that the withholding of the saline particles may cause a secretion of albumen instead of mucus."

In the cases that have come under my notice, the discharges from the intestines have assumed, in the first stages of the complaint, a mucous appearance; secondly, a mixed mucofibrinous character; and lastly, the evacuations have contained true fibrine. The evacuations of fibrine have been preceded by long-continued pain in the abdomen, and great irregularity in the temperature of the skin; highly sensitive to a damp atmosphere, causing spasmodic pains in the abdomen. When the epithelium covering the fauces and posterior nares is implicated in the disease, the patient suffers much from violent pain in the head, referrible to the region of the parietal bones, with extreme irritability of mind. There is a great tendency to acidity of the stomach, which is increased under the use of a liquid diet. The abdominal pains are always of a spasmodic character, and at times very acute, extending to the neck of the bladder and down the inner part of the thigh. The tongue assumes a white appearance, with indentations round the edges; sometimes ulceration of a phagedenic kind forms over the tonsil glands. The pulse is seldom altered, generally maintaining a steady healthy feel; the skin is often studded with numerous papillæ, especially over the chest, neck, and face; the urine denotes an anæmic condition of the kidneys. Occasionally such patients pass urine with evident traces of albumen, seldom containing a normal quantity of the phosphates. On an increase of fever or mental excitement, a larger quantity than natural of the lithate of ammonia is found; frequently the mucous membrane of the bladder is found thickened in these cases. The fæces, which are very seldom incorporated with the fibrin, are often very healthy in appearance, clearly showing a natural action of the glandular system. Although it is said by most authors that this disease is by no means fatal, yet I think I have seen it degenerate into atrophy of the intestines.

Causes.—In every case that I have

witnessed, I have invariably found the disease produced by the exhibition of mercury conjoined with the too frequent use of aperient medicine; mercury disorganises the blood by separating the fibrinous particles (M. Bauer observes that fibrine exists in the form of very minute white globules in the blood in a state of health: see *Philosophical Transactions*, 1820, p. 1.) Although mercury does remove depositions of coagulable lymph or fibrin, I am fully confident it also causes a tendency to deposition of lymph. Suppose there be venous congestion of an organ during the action of mercury, so as to interfere with the normal law of the capillaries, what will be the result? an interstitial deposition. I have not presupposed such a statement, the facts have been presented to me in the usual mode of investigation, and the more I observe of the complaint, the more I am convinced of the above truth. Such patients always experience an acceleration of symptoms from the use of mercury, particularly calomel even in small doses. The disease is also found in patients who are very readily salivated, so that it is just right to admit there may be a peculiarity of constitution when mercury puts on so untoward a form. I feel, in making the above observations, that I may subject myself to some controversy; but let me entreat any one who may doubt the statement, to investigate the disease for himself, before he comes to any conclusion. It is a fact known to those whose practice has enabled them to examine the blood of patients under a state of pytalism from the effects of mercury, that the blood of such patients is buffy, or, in other words, the fibrinous particles of the blood are found separated from the crassamentum.

Treatment.—It is necessary to pay great attention to the locality in which the patient resides, as the situation ought to be dry, and free from malaria. The clothing must be warm; flannel next the skin, and the feet protected with cork soles in the shoes; and what I very much commend is friction to the body or trunk with oil or lard every night, and tepid ablution with soap and water every morning: the muscular system should be regularly exercised, without fatigue. The diet should be spare and solid, consisting of bread and meat in the

form of a thin sandwich, with salt and aromatics. All stimulants are indirectly injurious: if the stomach be not irritable, or rather if there be no redundancy of acidity, milk may be given as a diluent with the greatest advantage. As a general rule, aperients are bad, leaving the patient very prostrate, but when indicated (that is, when large collections of fibrin are lodging in the intestinal canal as a source of pain) a tea-spoonful of castor-oil is the best purgative. Ammonia and soda are needful according to the acidity of the stomach, or rather when the urine contains a larger quantity than natural of the lithate of ammonia. Carbonate of ammonia should also be given as an antiseptic when there is torpor of the sensorium, indicative of a low character of fever. The mineral acids are to be preferred as tonics when required. An enema of warm water, gradually reduced to 50° Fah. is to be used every morning, and, according to the symptoms, narcotics are to be added. Should the effects continue despite of these means, the nitrate of silver ought to be used by way of injection per rectum, one-sixth part of a grain to be administered night and morning. I have never found any benefit from the use of turpentine, copaiba, benzoin, tar-water, or arsenic, nor by any counter-irritant. These cases may be assisted by an occasional hot salt water bath. In conclusion, the treatment should be of a negative character, by which I mean avoiding every thing that may interfere with the natural law of the part affected; or, in other words, let the organism of the intestines effect its own restoration. It is better to keep that principle in view during the treatment; yet, on the other hand, all irritants must be removed, and acute pain must be subdued. In the early stages of the complaint, when the evacuations are of mucous or mucofibrinous character, the hydriodate of potash, with morphine, may be given with advantage, the former in ten-grain doses night and morning, with half a grain of the latter at bed-time.

Crayford, Kent, Dec. 2, 1843.

CASE OF
EXCISION OF THE UTERUS BY
THE ABDOMINAL SECTION.

To the Editor of the Medical Gazette.

SIR,

MAY I beg the favour of your inserting in an early number of your valuable publication the following case of excision of the uterus by the abdominal section. Though the case terminated fatally, I do not shrink from publishing it, because I believe that in no other way than by a true statement of unsuccessful, as well as successful cases, can we ever hope to establish, on a proper basis, any principles either in medicine or surgery.—I am, sir,

Your obedient servant,

A. M. HEATH,

Lecturer on Midwifery in the Manchester School of Medicine and Surgery, and one of the Honorary Surgeons to the Union Hospital.

Manchester, Nov. 28th, 1843.

Jane Burns, æt. 43, unmarried, has never been pregnant, was admitted into the Manchester Union Hospital, under the care of Dr. Hardy, and was transferred to me by the consultation held on the 6th inst. The patient, low in stature, with a tendency to *en bon point*, with blanched cheeks and anæmiated lips, states that, during the last four years, she has suffered from excessive discharges of blood per vaginam, recurring at periods varying from three to four weeks, and continuing for the space of nine or ten days.

About twelve months ago her attention was first drawn to a fulness at the lower part of the abdomen, which, on more particular examination, she discovered to be caused by a tumor about the size of a large orange, and occupying the left hypochondriac region. She suffered no pain from the morbid growth; but its rapid increase in size, and excessive discharges of blood, induced her to consult a medical man, who sent her into the hospital, when she was submitted to a consultation of the medical officers.

Viewed exteriorly, the abdomen resembled that of a woman advanced seven months in pregnancy, the tumor being situated in the median line, and extending from the pelvis to a little above the umbilicus. It appeared firm

to the touch, and admitted of free motion in every direction.

The sensations communicated to the finger introduced per vaginam, were those of an unimpregnated uterus: the os tincæ being situated somewhat forward and closed, the fissure being transverse, and the cervix retaining its pyriform shape. When the finger was pressed against the os uteri, and the tumor raised by grasping it through the abdominal parietes, some motion of the uterus was perceived, which led to the supposition of the tumor being attached to that organ.

After repeated examinations, and most careful manipulations, by myself and colleagues, made at different times and in every variety of manner, the conclusion arrived at was the presence of an ovarian tumor; and it was our unanimous opinion that the condition of the patient, and the mobility of the tumor, made it a fair case for extirpation by the abdominal section.

Some preparatory treatment was then decided upon, with a view to the improvement of her general health, as well as to allow her to become accustomed to her change of situation. To improve the alvine secretions, which exhibited a deficiency of bile, occasional doses of blue pill and rhubarb were prescribed. The ioduret of iron was also recommended to be taken three times a day, and a mild nutritious diet was ordered to be supplied.

These objects having been attained, the patient was pronounced to be in a favourable state to undergo the operation, which was arranged to take place on Tuesday, November 21st, at 11 o'clock, A.M.

On this day the temperature of the operating theatre was gradually raised to 70° Fahrenheit. The physicians of the hospital, Drs. Chaytor, Black, and Hardy, having arrived, together with several other professional friends, and my surgical colleagues, Messrs. Ransome and Goodlad, being ready to lend me their efficient aid, the subject of the operation was placed upon the table, when an incision was made from a little below the ensiform cartilage to within an inch and a half of the symphysis pubis, in the median line, but deviating a little to the left opposite the umbilicus, cutting through the skin, adipose tissue, and superficial fascia, thus exposing the fascia trans-

versalis. A momentary pause was then made, to allow the small divided vessels to retract, and a ligature was passed round a small branch of the internal epigastric artery. A portion of the fascia transversalis, seized by the forceps, was then divided to admit the director, upon which the opening was enlarged sufficiently to receive my finger, which guided the bistoury in making the incision to the same extent as the external wound, the peritoneum being opened at the same time and in a similar manner.

The tumor now came into view, and was recognized as the uterus distended by solid matter; and this was rendered more certain by the introduction of a trocar. The size and solidity, with the rapid growth of the tumor, and the probable effects which would be produced by the next periodical discharge of blood, determined me at once to effect its removal *en masse*. Having passed my hand over the fundus of the uterus, and behind it, I raised it from the abdominal cavity, when it was sustained by Mr. Goodlad, while two double ligatures were passed, by means of a sharp-pointed aneurism needle, through the cervix uteri, immediately below the circumference of the tumor. Each ligature was then firmly tied, so as to include one-half of the neck of the womb and broad ligaments. The parts were then excised and removed. No bleeding ensued from the cut surface; indeed, throughout the operation, not more than three ounces of blood were lost; and after the first division of the skin, few complaints of suffering were made by the patient herself.

The intestines, which had escaped, were replaced *in situ*, and the abdominal parietes brought together by the interrupted suture at seven points. The edges of the wound were kept in apposition by applying narrow strips of adhesive plaster. To effect this object with more certainty, a large compress of lint was placed on each side over the recti muscles, and then secured by a broad flannel binder, which was tied firmly round the abdomen. The patient was now carefully removed to a bed which had been prepared for her in the operating theatre. Vomiting came on, and a draught containing morphine acetatis, gr. ss., which had been given to her, was instantly rejected. She, however,

complained of severe pain about the umbilicus, for which a couple of pills, containing pulv. opii. gr. ij., ammon. carbon. gr. v., were swallowed and retained. The disposition to vomit continued; and after the lapse of half an hour some fluid was ejected, but the pills were not discoverable in it. At this period the pulse was 120, soft and fluctuating.

At 4 o'clock P.M. I met Mr. Ransome in consultation. The pain being very severe throughout the whole of the abdomen, and fearing again to excite the stomach, we determined on the exhibition of a starch enema with morphine acetatis, grs. ij. dissolved in it.

The countenance speedily assumed a placid appearance, the pain began to diminish, the pulse was 80 and soft. Respiration performed normally, the skin perspiring freely. Temperature of the room 73° Fahrenheit.

7 P.M.—Has had some sleep; is now composed, and states herself to be much easier; pulse has risen to 100, still soft; has passed urine to the amount of 3vij. without effort and without distress. Temperature of the room reduced to 70° Fahrenheit.

9 P.M.—Enjoyed a sound sleep for an hour and a half; abdomen free from pain; is cheerful, and expresses her gratitude for the trouble taken in her behalf. Pulse as at last report.

11 P.M.—The pulse has risen to 100, remains soft and tolerably firm; complains of the heat of the room, which is to be reduced a few degrees.

Half-past 1 A.M.—A few spoonfuls of arrowroot again roused the stomach. Pulv. opii, gr. j. was administered. From this time she began to sink; the pulse became feeble, the extremities chilled, and at a quarter before 5 A.M. she expired without a struggle, having survived the operation seventeen hours.

Sectio cadaveris, performed twenty-nine hours after death.—On removing the flannel roller and plaster, union of the cut surfaces of the abdominal parietes was observed to have taken place to the extent of an inch at the umbilicus, the adhesion being strong enough to retain the edges together after the sutures had been severed.

Towards the lower part of the wound the peritoneum had become adherent, requiring some force to separate it. The intestines, jejunum, ilium, and colon, were much distended with flatus;

spots of increased vascularity presented themselves in many places, though some difficulty was experienced in distinguishing these from patches which had become tinged by contact with coagula, which had stained the mesentery, rendering the whole of a purple colour.

About fourteen ounces of blood were taken from the cavity of the abdomen; on searching whence it had escaped, we found it to have oozed from the cut edges of the uterus, though no disposition to hæmorrhage from this source was evinced on making the section; notwithstanding the ligatures remained tightly constricting, and completely surrounding, the remains of the organ. The intestinal cellular tissue was filled with clots, which clearly proved to my mind that the hæmorrhage had taken place from no large vessel, to which a ligature might have been applied.

The bladder and rectum were both active, not having been disturbed or otherwise injured. The spleen was remarkably soft; so much so, that when placed upon the table it wanted sufficient consistency to maintain its form.

The kidneys were both much softened at the cortical part, of a brown colour, as if drained, or rather freed from blood by washing.

The liver had a peculiar appearance; in colour resembling clay, and, like every other organ examined, displayed the almost anæmiated state of the system. The thoracic viscera were healthy; the heart soft, pale, and flabby.

Description of the tumor.—The excised mass was found to consist of the whole body of the uterus, enveloping a dense adventitious structure. It was of a perfectly smooth, uniform, globular shape, presenting no trace of salient points; weighed six pounds; had a diameter from above to below of seven inches, and a circumference, in the transverse direction, of 20 inches.

The walls of the uterus were increased generally to about three quarters of an inch in thickness, whilst the fibrous structure was as fully developed as during the dilatation of advanced pregnancy.

The tumor took its rise apparently in the muscular structure immediately beneath the mucous membrane, seeing that some few only of the fibres could be traced into it for a short distance; and had proceeded downwards from the fundus, and more especially on the

left side, pushing before it the mucous membrane which invested its globular lower extremity with a smooth shining surface.

The adventitious structure, during its growth, had been subjected to severe compression; it was firm, hard, exceedingly dense, and had something of crispness on incision.

Its general colour was yellowish-white, without much vascularity, and it was divided into definite irregular lobules by bluish semi-transparent lines, not unlike the bands which traverse true scirrhus formations. The structure was too compact to permit any view, with the unassisted eye, of any cystiform character; and so far as the tumor had been divided, there was no tendency to softening in any part.

It was found that about two inches of the uterus had been left by the incision, and every trace of the diseased structure removed. The os was of the natural virgin size and form, neither patulous, hardened, nor fissured; and its lips were uniformly smooth, rounded, and plump.

The cervix was not shortened, for the condition which had left the os unaltered in form would not have admitted the cervix to be much spread out.

A few remarks may not be out of place on the error in diagnosis, and the expediency of the subsequent removal of the tumor.

As to the first point, it had suggested itself to many of those who had examined the case as well as myself, that there was something of anomaly in the bloody discharge, and the central situation and firm character of the tumor, and that it was just possible the uterus itself might be the enlarged organ. But the discharges, although large in quantity, were always periodical, and such as not unfrequently occur, therefore, at the season of catamenial decline, altogether independently of any structural lesion of the womb. Again, the os and cervix, on repeated nice examinations, gave evidence of no deviation whatever from the normal condition, a circumstance of rare occurrence with the kind of tumor which was subsequently found to exist.

The tumor was so uniformly smooth and rounded that the suspicion of a large hard fibrous growth of the uterus could hardly be entertained, seeing that

such swellings are almost invariably very irregular and nodulated in form. The uterus was examined stethoscopically, but neither by that, nor any other means, could any suspicion be had of pregnancy; and the diagnosis of ovarian disease was confirmed by the manifest enlargement which seemed to be taking place in the swelling during the few weeks which preceded the operation. On the other hand, a firm, dense, unfluctuating mass, and a more or less central position, are well known by those who have examined many of such cases, not to be incompatible with enlarged ovary.

After the true source of the swelling had become evident (a trocar having been previously thrust in by which the character of the tumor was ascertained) the question arose, whether, since a large part of the danger had been already incurred in the abdominal section, exposure, and manipulation of the bowels, &c. the greatest probability of ultimate good was not in favour of the extirpation of a growth which was rapidly sapping the constitutional powers by hæmorrhage. Instances were on record where such a step had been taken from intention; many cases had occurred of successful division of the uterus through the vagina, and as far as the peritoneum and ligature of the pedicle were concerned, there appeared to be no great increase of risk in the excision of the uterus over that of the ovary.

The diseased growth was evidently a specimen of what has been called the fibrous, and by Dr. Ashwell the hard, tumor of the uterus, who has given a clear account of its structure in the 6th No. of Guy's Hospital Reports; and although not high in the scale of malignancy, it partook to some extent of the character of such transformations. The earlier bleedings in such cases ooze from the mucous membrane which invests the free portion of the tumor, whilst the subsequent hæmorrhage will flow in increased quantity from the softening and disintegration which never fail to attend the onward progress of such growths if life be sufficiently prolonged for their development.

A FEW OBSERVATIONS

CONCERNING THE

ILL EFFECTS ARISING FROM
THE CIRCULATION OF CERTAIN
PARTICLES IN THE BLOOD,

*Being the abstract of a Paper read before
the London Hospital Medical Society,*

By G. BETTS, Esq.

(For the Medical Gazette.)

AFTER briefly enumerating the several opinions relative to the formation of consecutive abscess, cancer, &c., the author proceeded to make a further inquiry into the subject, by considering it under the three following heads:—

1st. What effects follow the introduction of foreign particles into the circulation?

2d. Are such effects, when we observe them in disease, at all to be associated with a like cause?

3d. How do such effects manifest themselves?

In connection with the first inquiry, it is necessary to premise that there are three principal series of capillaries in the higher animal economy, each being the termination of a distinct set of vessels. Thus there is a *systemic series*, in which the arteries terminate; a *pulmonic series*, in which, through the heart, the systemic veins terminate; and an *hepatic series*, in which the portal or abdominal visceral veins terminate: and upon the introduction of foreign particles into any vessel of the body, we get its effects manifested in that particular system in which the vessel terminates. The experiments which have led to this conclusion were here detailed, and were principally made by injecting mercury into different parts of the circulation; but the author had performed a corresponding series, using pus instead of mercury, and he still found that it produced a certain amount of inflammation and abscess in the tissues and organs supplied by the capillaries in which the vessel terminated. Thus pus thrown into the mesenteric veins produced abscess of the liver; when injected into the crural or other systemic vein, it occasioned abscess of the lungs; when the amount of pus thrown in was considerable, it produced almost instant death, by blocking up the capillaries, and so stopping the circulation in the lungs; when introduced

into the arterial system, it caused abscess in the tissues supplied by those vessels: and the author had hoped to have completed some parallel experiments by the introduction of the cancer cell into the circulation; but still these are sufficient to show that the pus globule, among other particles, is arrested at the capillaries, and gives rise there to abscess, &c.

2d. *Whether such, when we observe them in disease, are at all to be associated with a like cause?* It is pretty well agreed by pathologists that suppurative phlebitis is one of the most frequent causes of disseminated abscesses; but to review the several systems, the investigations of Arnott, Cruveilhier, Dance, and others, have left little doubt but that abscess of the lungs is generally, and perhaps always, associated with the suppurative inflammation of some vein, and of which accidents to bones are the most frequent cause. Hepatic abscess also often occurs after operations implicating the viscera, and Dr. Budd has recently directed attention to its association with dysentery, and its probable origin in the suppuration of one of the small mesenteric veins. Now these, with other premises, warrant the opinion that suppurative phlebitis, or, in other words, the introduction of pus into the circulation, is almost always the precursor of these abscesses.

In reference to the third question, as to *how these effects manifest themselves*, the author had but to direct attention to the relative measurements of the capillary vessels and the pus globule or cancer cell, in order to show that the latter were much too large to pass the capillaries; and if it stopped there, what effects would result? Why, experiment told us that they acted as other irritants, producing inflammation and abscess; and that their own capability of multiplying (like that of other cells), particularly in reference to pus, was sufficient to account for the rapid accumulation of the matter, without at all supposing that the whole of it was brought there and deposited ready formed. There is also great reason for believing that other morbid effects, as tubercles, &c. result from the circulation of their particular cell globules, which, moreover, may manifest a disposition to become better and more fully developed in certain tissues.

LIGATURE OF THE SPERMATIC ARTERY

FIRST SUGGESTED BY HARVEY.

To the Editor of the Medical Gazette.

SIR,

IN my work on the Diseases of the Testis, &c., lately published, I have unintentionally committed an act of injustice to the merits of a distinguished individual, by an oversight, for which I am anxious to take an early opportunity of making amends. The omission alluded to was detected by Mr. Soden, of Bath, and kindly pointed out to me in the following letter, for which, as well as for the flattering expressions contained in it, I beg to tender him my sincere thanks.

“Sir, — Although I have not the honour of being personally known to you, I am induced to address you in consequence of the pleasure I have derived from the perusal of your valuable work on Diseases of the Testis. Few professional works, indeed, have afforded me so much gratification as this production of your pen. Its historical department is extremely interesting, and evinces such a liberal desire on your part to do justice to the merits of all your predecessors, that I trust you will excuse the liberty I take in referring you to an authority that appears to have escaped your vigilant and comprehensive research. You give the credit of originality to Maunoir for the application of a ligature round the spermatic artery, as a substitute for extirpation of the testicle. You are perhaps right in considering this operation as of little practical value; but if you had been acquainted with the following passage in Harvey’s work on Generation, I am sure you would have paid a tribute to the claims of our immortal countryman, the discoverer of the circulation, who not only suggested the plan of tying the spermatic artery in certain cases of enlarged testis, but actually and successfully carried it into effect.

“Extract from Harvey on Generation. English edition. London, 1653.

“‘Having had an eye upon this employment of the arteries, or circulation of the blood, I have sometimes perfectly cured exceeding great herniæ carnosæ,

beyond all expectation; providing only that the little artery being tyed or cut off, no nutriment or spirit might have accessions to the part affected; by which it fell out, that the fatal tumor was afterwards easily extirpated either by incision or adustion. A certain man, besides other infirmities (and of this story I can produce many testimonies), had a sarcosis or flesh, tumor in his scrotum or cod, bigger than a man's head, hanging down to his knees; and from it another hernia carnosae, as thick as one's wrist (or a cable), passed into his abdomen, so that the disease growing to so great a height, no man would undertake the cure by incision, or otherwise. Yet I perfectly cured this so vast excrescence, which so much distended the scrotum and encompassed the testicle, by the means aforesaid; and yet left the leading and preparing vessel to the use of the testicle, without any prejudice or touch upon the other vessels descending into the scrotum by the tunica vaginalis, or coat of the testicles so called. But these and other cures accomplished clean beside the common opinion, I shall, in my *Physical Observations* (if God grant me life), discover at large.' (p. 113-114.)

"It may not be quite clear what was the precise nature of the disease which Harvey treated in the foregoing case; but I think he intended to tie the spermatic artery, leaving the vas deferens entire, in the expectation that the morbid part would be absorbed without destroying the function of the testicle. The case is curious; and it appears to me surprising that it should have escaped the observation of the numerous and distinguished authors who have written on the physiology and pathology of arteries since the commencement of the present century, but I am not aware that it has been noticed by any of them. The proposal to tie the thyroid artery in bronchocele, and to promote the absorption and arrest the growth of large tumors by putting a ligature round the vessels that nourish them, has been generally regarded, I believe, as a modern suggestion; but it is evident that Harvey was acquainted with the principle on which such treatment has been recommended. Harvey's *Physical Observations* were never published; and it is to be feared they were lost, with his other papers, during the troubles in

the time of Charles I. The work on Generation was edited by Sir George Ent, who, in the preface, gives an interesting account of an interview with the author, during which Harvey pathetically lamented the disastrous state of public affairs, and at page 418 he feelingly alludes to the loss of his manuscripts. I will not, however, detain you longer, but beg you will forgive this intrusion on your time; and believe me, dear sir,

"Very truly yours,
"JOHN S. SODEN.

"Bath, Nov. 18, 1843.

"To T. B. Curling, Esq."

That the application of a ligature to the main artery supplying a particular part, morbidly enlarged, should cause that part to waste, if such a notion had never been entertained before, would not, in the present advanced state of physiological knowledge, be regarded as anything extraordinary; but when we consider the ignorance on these subjects which prevailed at the time this idea entered the mind of Harvey—that at that period the circulation and the distinct offices of the arteries and veins had only just been discovered—the suggestion must be viewed as indicative of a mind of no ordinary sagacity, and as showing how ready this great man was to make a practical application of the results of his grand discovery; and although this plan is not likely to be applied with benefit to any of the diseases of the testis, the principle upon which the treatment was founded is a valuable one, and has, in other cases, as for instance in bronchocele, been successfully acted upon.

I shall be obliged, sir, by your giving insertion to this communication, which may prove interesting to many of your readers. It will tend to shew that the writings of some of our great predecessors, now neglected, may be studied with advantage; and it may prevent others from falling into the error that I have committed, of describing as a novelty in the 19th century, that which was suggested and practised in the 17th.

I am, sir,

Your obedient servant,
T. B. CURLING.

37, New Broad Street,

Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE INFANT MARTYRS.

A PHILANTHROPIC physician in the west of England has given this quaint title to his reports on the burning of children, communicated to the Royal Institution of Cornwall.

On examining the mortality of various parts of England in 1838, it appears that in certain portions containing a population of nearly three millions, the deaths by burning were 723, or 1 in 4085. If this were the average of all England, the deaths from this frightful cause would be about 3,500 annually. Happily, however, this is not the case. In Norfolk and Suffolk the deaths by burning are 1 in 6000 of the population; and in the metropolis only 1 in 7000. On the other hand, in the mining districts of Stafford and Shropshire, the deaths from this cause were about 1 in 2000 of the population!

Yet, although the returns show clearly that mining operations increase this species of mortality, they show with equal clearness that the majority of those who die by burning, perish, not by the explosion of mines, nor by the conflagration of houses, but simply by their clothes catching fire. In some cases this may be inferred by reasoning. Thus, among the 723 deaths by burning above mentioned, 541 occurred under ten years of age. But, in some of the more accurate returns, the thing is expressly stated. Thus, of 94 who perished by burning in South Staffordshire, 81 were destroyed by their clothes catching fire; and of these 61 were under ten years of age.

Under the age of one year, the number of deaths from burning is very small, as the mere infant can rarely

get to the fire. Up to the age of five, the danger from this source increases every year; for vivacity, curiosity, and activity, are daily augmented, while the lessons of caution and obedience have scarcely been learned. After this period, there is a gradual decrease, till old age brings back the weakness and the dangers of childhood.

Age has so great an influence in this species of casualty, that out of 58 deaths from this cause in six Cornish Unions, 48 occurred between the ages of 2 and 8.

In the London Bills of Mortality, it appears that the proportion of deaths by burning has increased portentously since 1800, "advancing," says Dr. Barham, "*pari passu* with the use of cotton goods."

This must, no doubt, have had a considerable share in the change; but it is difficult to attribute the whole to this cause, especially when we find that even in the last century the proportion was more than twice as great in the latter as in the earlier half; while we can hardly think that the use of cotton was very common among the lower ranks before 1800. A change of social relations may have contributed to the increase, for the greater bustle and competition of modern life have probably compelled more mothers to leave their children unwatched and unguarded.

The deaths from burning are, of course, most frequent in cold weather, being inversely as the deaths from drowning. There is a great resemblance in the history of many cases of burning, and the following is a sample of a large class.

"A little girl, four years of age, had been drinking tea at a neighbour's; and having dropt some on her pinafore, was holding it to the fire to dry, when it became ignited. Another girl, about three years old, was the only person in the room at the time, but the screams brought two young women down stairs

almost immediately, and they tried to extinguish the flames, but from ignorance of the course proper to be pursued, quite ineffectually. The child died in a few hours."

Murder by burning is very rare. A case, however, occurred at Truro, some years ago, where it was suspected. A dissolute woman had locked up her child in her room, alone, where it was found, burned to death, some hours afterwards. "On accurate examination by Dr. Barham, in conjunction with Messrs. Bullmore and Spry, some portions of the tinder were discovered in the lower part of the windpipe. These must have been drawn in with the breath during the last moments of the child, whose mouth and face had evidently been enveloped in his burning clothes." Dr. Barham adds, "this was the principal circumstance which prevented the committal of the mother for murder."

We can readily believe that the woman was innocent, but, as a mere matter of speculation, could not a murderer also have wrapped the child's face in its clothes?

As to the means of preventing these fearful catastrophes, they are obvious enough; the history of the case of the little girl, which we gave above, will supply hints for the most effectual remedies. In the first place, children of a tender age should not be left alone in a room with a fire. If the feverish hurry of modern existence renders the observance of this rule impossible, the next best thing is a fire-guard, or a high fender fastened to the sides of the hearth. Dr. Barham thinks that the Society for Promoting Christian Knowledge and the Polytechnic, might unite in providing succinct instructions for extinguishing clothes on fire, and also in furnishing specimens of cheap fire-guards and fenders. The sufferer, instead of being allowed to run about the room, should, of course, be instantly thrown on the floor, and wrapped up in

a rug or blanket. It is also advisable to throw cold water upon him, or to apply a wet towel firmly to the burning clothes.

If a proper guard cannot be obtained for the fire-place, Dr. Barham proposes some sort of imprisonment for young children as an indispensable substitute. This is a painful recommendation, and many would think the remedy worse than the disease, or, at least, than the *chance* of the disease. We should not like to see restraint chairs in every cottage.

Dr. Barham would also wish cotton goods to be renounced, and the ancient woollen garments to be again worn; but he acknowledges that this is a wish of difficult accomplishment. Society has advanced from woollen to cotton, and does not willingly go back :

————— revocare gradus —————
Hic labor, hoc opus est !

But it has been proposed that linen and calico should be made less combustible by being dipped in a chemical solution; and we agree with Dr. Barham that this proposal is worthy of consideration.

Lastly, if the pinafore, instead of "floating wild as mountain breezes," is fastened down so as to keep the dress in contact with the body, without impeding motion, the risk is considerably lessened.

Mr. Edward Osler, who has written some observations as an *envoy* to Dr. Barham's little pamphlet, insists with vigorous earnestness on the vast number of children annually sacrificed by fire, and the equal multitude, who, though not burned to death, might envy the victims who perish. He describes the progress of a severe burn, its slow cure, its hideous cicatrix, and the contraction of the injured limb requiring the knife of the surgeon to restore freedom of motion.

"Such are the evils we are called upon to deplore and prevent—thousands of

children destroyed by a frightful and torturing death; thousands more escaping with life, but under circumstances which make life hardly a blessing; tortured, disfigured, and crippled."

He, too, urges the use of stuff pinafores which the decent poor would provide for themselves, and which might be given to the necessitous. The clergy, too, and other philanthropists, might give a word of advice, of caution, or even of reproof, when a child is seen wearing dangerously inflammable clothes.

Mr. Osler wishes, moreover, to see a tract on the subject issued by the Christian Knowledge Society, and to have a page devoted to it in the popular school-books which are sold by myriads.

As an application to burns he recommends oil of turpentine. On this point, as our readers know,

Chirurgi certant, et adhuc sub judice lis est.

We should be more inclined to recommend the laity to use scraped potato, or flour.

This pamphlet will not be without advantage to the community.

What Pope says of vice, or moral evil, that to be hated it needs but to be seen, may be applied with equal truth to physical evil. Give a faithful portrait of its lineaments, and mankind will unite to repel its aggression. Dr. Barham and Mr. Osler have, therefore, done some service to the state.

INCREASE OF DISEASE AMONG THE POOR.

THE District Surgeons have appended to their Annual Medical Report to the Directors of the Town's Hospital the following note:—

"From the above Report, it is evident that disease generally has been fearfully on the increase for the last twelve months. In 1841-2, 5,296 cases received medical relief; this year, 19,085 cases; increase this year, 13,789 cases. Of this year's report 12,967 were cases of a peculiarly distressing epidemic fever, and 736 cases of typhus fever. Of

the former 12,967 cases, 12,397 were treated at their own homes, and 570 sent to the Royal Infirmary. Of those treated at home 304 died, being in the ratio of 2·363 per 100 cases.

"The number of typhus cases this year exceeds those of last year by only 5 cases, the number for 1841-2 being 731; for 1842-3 being 736. The mortality, however, of the latter exceeds the former—the numbers being, 19 for 1841-2; and 34 for 1842-3.

"From Nov. 1838, till Nov. 1842, there were (according to the medical records of the hospital) 18,927 cases that received medical relief. This year, however, exceeds that number by 158 cases, and allowing a medium of six visits to each case (which is much under the truth), it gives the gross amount of 114,510 visits given by the district surgeons to the city poor during the last twelve months."

Independent of the alarming fever now prevalent, there has been a great increase of disease generally for the last twelve months. Thus in 1841-2, exclusive of fever cases, there were treated at home for other diseases 4,565 cases; while in 1842-3, there were 5,382—being an increase of the enormous number of 817 cases.

Frightful as this picture is, still it is gratifying to find that something has been done, and is still doing, in order to check the ravages of disease, and alleviate the sufferings and privations of our pauper population. About three months ago the district surgeons recommended to the Directors of the Town's Hospital the propriety of affording to the most necessitous of their pauper patients immediate assistance in the shape of wholesome food, in addition to the ordinary means of relief, to which proposition the Directors at once kindly assented, and placed at their disposal a supply of penny tickets for distribution,—the Directors justly considering that their medical officers were the best qualified, from their personal knowledge of the circumstances of the poor, to discharge this duty in a discriminating and efficient manner.

This promiscuous charity on the part of the surgeons has amounted weekly to upwards of £20, and has been the means of imparting relief to thousands of our fellow-creatures whom want and disease had reduced to the extreme of wretchedness.

As a matter of economy, the advantage of this plan will be apparent from the fact, that if the Directors of the Town's Hospital had not acted in the liberal manner they did, it is believed that at least a third of the 12,397 cases of fever—viz. 4,699 cases—must have been sent to a fever hospital by the District Surgeons to keep them from starvation; which, at 15s. per case (the sum charged for fever cases by the Royal Infirmary), would

have amounted to £3,074. 5s. instead of £283. 15s. 8d. being the sum actually distributed by the medical officers for the last three months.

The public cannot fail to perceive the immense amount of labour performed this year by the 17 District Surgeons—a duty, the onerous, disagreeable, and dangerous character of which can only be fully estimated by a personal inspection of those wretched hovels of disease and penury which but too plentifully abound in this city. In these dens (for they deserve no higher appellation), many of which do not exceed from 6 to 9 feet square, whole families were found by the surgeons (all affected with fever), consisting sometimes of 9 individuals, stretched upon the floor, without either bed, bedding, fire, or even a morsel of food but that which was daily distributed to them by the Visiting Surgeon. In consequence of the above arrangements on the part of the Directors of the Town's Hospital, however, the state of the diseased poor has been vastly ameliorated.

CONSUMPTION CURED BY NAPHTHA.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by your correcting a mistake which appeared in the short account I sent your journal, of a case of consumption cured by naphtha. In the published account it is made to appear that the patient applied for admission to the Colchester Hospital, and was refused in consequence of his labouring under phthisis in the last stage. This mistake arose from my having mislaid a note I received from Dr. Baker on the case, which I have since found, and which is as follows:—

“I considered Perry to be labouring under confirmed consumption, and intimated as much to the Rev. Mr. Leigh (the clergyman of the parish), as a reason for not sending him to the Colchester Hospital. If cases like this can be cured by the use of naphtha, it will be a new era in medicine.”

This explains fully the misapprehension on my part, which appeared in the first statement. I wish further to add, that I saw Perry a short time since, when he told me he continued quite well.—I remain, sir,

Your obedient servant,

A. G. PROCTOR.

Dec. 5, 1843.

SUPPRESSION OF HÆMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

THE hint of “A Student” in reference to the suppression of hæmorrhage, contained in your journal of the 27th September, has induced me to send you the following remarks.

I was called, some time ago, to see a stout middle-aged man, who was bleeding profusely from the nose, and who had had several similar attacks during the two preceding days. He was in bed; but I desired him to sit up, and, as lately recommended, to raise the arm of the affected side above his head: he had only done so for a few seconds when the hæmorrhage stopped, and he fainted.

Here the flow of blood to the head was so far diminished by the erect posture and the elevation of the arm, as not only to arrest the bleeding, but, at the same time, to induce syncope. Might not the practice, then, be extended from cases of epistaxis to cases in which we are desirous of producing fainting, and that with as little loss of the vital fluid as possible? In acute inflammations, in strangulated hernia, and previous to the reduction of dislocations, the patient is bled in the erect position to faintness; and may not the elevation of the arm, after the commencement of the bleeding, be instrumental in producing the desired effect?

As the suggestion is simple, it is hoped that some of your readers may be induced to make trial of it, and communicate to you the results of their experiments.

I am, sir,

Your obedient servant,

JUVENIS.

QUARTERLY REPORT OF THE

OBSTETRIC DEPARTMENT OF THE PHILADELPHIA DISPENSARY,

For First, Second, and Third Months, 1843.

By JOSEPH WARRINGTON,
Obstetric Physician.

FORTY-FOUR women have been delivered, all at or near the full term of utero-gestation, except one, in which the ovum, having been developed to the sixth month, was expelled at the termination of the seventh.

The average duration of labour, in thirty-nine cases, was fifteen hours, twenty-six minutes; the extremes being one and a half, and sixty-four hours.

The average amount of time required for the spontaneous delivery of the placenta, in

thirty-seven cases, was ten minutes; the extremes being five, and sixty minutes.

Manual assistance was afforded for the delivery of this mass in three instances, in which the disk presented so large a surface to the orifice of the uterus, that it could not pass through it until one edge was drawn down by the finger after the patient had made ineffectual efforts for extending it, in one instance fifteen minutes, another at twenty-five, and the third at forty-five minutes subsequent to the expulsion of the fœtus.

Forty-five children have been delivered, one woman having twins.

Twenty-nine of these children were males, and sixteen were females.

The vertex of the cephalic extremity of the fetal ellipse presented in thirty-two instances; of these, nineteen were in the first position, and seven in the second.

One child, developed to the sixth month, but born at the end of the seventh, presented the breech in the fifth position.

One of the doublets presented the dorsum; it was converted by the use of a hand into the second position of the breech.

The umbilical cord was noted in one case to be about one-half the usual length, measuring ten inches.

One child had a slight deformity of the pedal articulation, for the correction of which appropriate dressings have been applied.

One child also had exomphalos, which is improving rapidly under a compress and roller.

The os uteri in one case, during the first stage of labour, continued so rigid as to render free bleeding necessary to promote relaxation.

There were two instances of irregular contractions of the uterus for about two weeks before the termination of labour; in one of these the os uteri was observed to be partially dilated about eight days previous to delivery.

In the second stage of the labour, the entire duration of which has been noted to be sixty-four hours, forty grains of ergot were administered, without, however, any marked effect in increasing the expulsive action of the uterus.

The forceps was used in one case to deliver from the superior strait of the pelvis a child, the occipito-mental diameter of which measured seven, the occipito-frontal six, the biparietal three and a half, and occipito-bregmatic three and a half inches.

This instrument was used also in a primiparous female, for the delivery of a child, the head of which had become arrested at the inferior strait. The child weighed ten and a half pounds.

There were three instances of hæmorrhage after delivery. Free fiction, regular com-

pression, and the ergot, in tincture or substance, were resorted to. The flow became speedily arrested in two cases; in the third, however, the atony of the uterus was so great, that its contractions could not be reproduced until the hand had been introduced to stimulate its internal surface. Recovery was rapid in the two first instances; but in the third the patient suffered much from the usual consequences of excessive loss of blood for several days.

There were five cases of attacks of inflammation of the peritoneum, uterus, or its appendages, after delivery. In three of them the disease was quickly arrested by prompt and free venesection, cathartics, and anodyne diaphoretics. One continued through a number of days, though actively depleted, both generally and locally, and one resisted the action of all treatment.

The patient was badly accommodated in one of the densely inhabited houses on the bank side of Front Street, and had suffered much from moral and physical causes, both before and subsequent to her parturition. She died on the sixth day after delivery. All the other women recovered.—*Philadelphia Medical Examiner*.

REMARKABLE CASE OF CALCULUS.

M. SEGALAS lately communicated a case to the Academy of Medicine, which tends to show that at present the difficulties of lithotomy are not so much mechanical ones, as difficulties resulting from the complications of the calculous disease.

The head of a respectable family came to Paris, four years ago, to seek advice for a hæmaturia and some other affections of the urinary passages.

M. Recamier, who was first consulted, sounded, to see if there was a stone in the bladder; but instead of a stone he found a fungus. A few days afterwards M. Ségalas made the same examination with the same result. In consequence of this, medical means alone were employed, and the patient went home, and continued to live there, with nearly the same symptoms. After some time, however, the hæmaturia, which had hitherto appeared as much when the patient was at rest as under other circumstances, began to come on more especially after exercise, just as if some foreign body had been added to the fungus. The calls to make water became more and more frequent, the pain more and more acute, so that the patient resolved to return to Paris to seek for surgical aid.

M. Ségalas ascertained, by sounding, the presence of a stone in the bladder, and after some days' preparation, considering the good constitution of the patient, and his extreme

repugnance to lithotomy, he performed a first *séance* of lithotripsy, in the presence of M. Gouraud, the physician who usually attended him. It was very easy, very short, and but little painful. For some time, matters went on perfectly well; but on the sixth day, when straining at stool, the patient was attacked with apoplectic symptoms. These were at first encountered with some appearance of success by MM. Récamier and Gouraud, but they afterwards grew worse, and death took place a week after the attack.

Post-mortem appearances.—The bladder, which was hypertrophied, contained a fungus as large as a walnut, and a heart-shaped stone nearly as big as a hen's egg. This calculus was divided into two large pieces and several small ones. The kidneys were inflamed, particularly the left one, and there was granulated pus upon their surface. There was an extravasation of blood in the right hemisphere of the brain, at the union of the posterior third with the two anterior thirds, besides an hydatid cyst in the corresponding ventricle.

Thus it was possible to begin the operation of lithotripsy without difficulty, in spite of the size of the stone, in spite of the presence of a fungus; but even putting aside the apoplexy which carried off the patient, the complications of the calculous disease were of themselves beyond the reach of art.—*Gazette Médicale.*

CLINICAL OBSERVATIONS ON THE CONSEQUENCES OF STRICTURE OF THE URETHRA.

By B. PHILLIPS, F. R. S.

AMONG the more serious and frequent of the affections to which stricture of the urethra may give rise, are an altered condition of the mucous membrane of the urethra behind the contraction, disease of the prostate, of the testicle, of the bladder, of the kidney, and of the rectum.

Even if we had no opportunities of ascertaining, after death, the state of the urethra between the stricture and the neck of the bladder, we might naturally expect that it must suffer from the frequent and urgent efforts to force the urine through the contracted part, and the irritation kept up by the constant presence of a certain portion of the fluid which is commonly retained there when the effort has ceased. However, the opportunities of making such observations after the death of the patient are, unfortunately, by no means uncommon.

It is only a few days ago that you had an opportunity of witnessing the state of that portion of the urethra, in a man who, during treatment for stricture, was attacked with pneumonia, from which he died. In the urethra two strictures were found; one about two inches from the orifice, which had been passed, one near the bulb, which had not been passed, and which was very close. The portion of urethra behind the latter stricture was thickened and rough, almost fungous; the prostate was enlarged, its ducts very open, and when pressure was made upon that gland a turbid fluid escaped in considerable quantity. Pressure on the vesiculæ seminales caused the escape of a muco-purulent fluid, and the vesicles them-

selves were much thickened. The inflammation had not extended to the testicle; but had he lived longer, this would most likely have happened; for he had complained of uneasiness at the back of the testicle for some days before he died.

In many cases the consequences of this pressure and irritation are very serious: the posterior part of the canal—that behind the stricture—may become dilated even to the size of an intestine; and indeed it has been proposed in such cases, when there is complete retention, and when no instrument can be passed along the urethra into the bladder, to puncture the urethra at this point instead of puncturing the bladder. When the urethra becomes thus dilated (and although frequently described, I do not think it is of common occurrence), the neck of the bladder loses its power, and the urine will then dribble away through the stricture: the mucous membrane suffers; it becomes affected with chronic or subacute inflammation, and may give way so as to allow of the escape of a small quantity of urine into the cellular tissue, in which violent inflammation is quickly set up; but it almost always determines sloughing of the cellular tissue, with which the urine gets in contact, and most serious mischief ensues. If the quantity of urine which escapes be considerable, it may infiltrate a great extent of cellular tissue, even passing to the inguinal and inferior abdominal region. In these cases a knowledge of the anatomy of the aponeurosis or fascia of the perineal region enables you to determine the probable point of the urethra which has given way, and also guides you as to the depth of your incisions to facilitate the discharge of the extravasated fluid; for in all such cases the first point is to get rid of the irritating fluid, and this can only be done by giving it the utmost possible facility for escape. In some cases, where the quantity of urine which has escaped into the cellular tissue is small, the symptoms and

the consequences are much less serious: a few drops only have passed; inflammatory action may be set up around, so as to form a kind of sac, and prevent further infiltration. After a time the patient may direct your attention to a small, pretty well-defined tumor in the perineum; you puncture it, and a little pus mixed with urine escapes. The cavity being lined by a membrane something like that of an ordinary canal, the opening manifests no disposition to close, and a very little urine may pass along it whenever the patient tries to empty the bladder. In many cases it will close when the urethra is restored to its proper size; in others it obstinately remains open. In all such cases there is reason to fear that a certain portion of urine will pass along this fistulous canal at each attempt to make water; and to prevent this either a catheter must be introduced whenever the patient desires to make water, or the instrument must be retained for some time—until, indeed, we have reason to think the accidental canal is closed. In some cases the constant presence of an instrument cannot be borne; and, indeed, it tends to keep up irritation in the fistulous canal: if this be so, it may be that the patient will be less irritated by introducing the instrument whenever he wants to make water. Even when no urine passes along the fistula, it sometimes resists all attempts to induce it to close.

Under such irritation as we have described, the prostate is very apt to suffer. It may be that it proceeds no further than to excite the organ to increased action, a larger quantity of its proper fluid than is natural being secreted and poured into the urethra; and in those cases the ducts are sometimes greatly dilated. It may be that the organ becomes enlarged; and then, by pressing upon neighbouring organs, it may cause much discomfort and distress. It may, by projecting into the rectum, interfere with the passage of fecal matter; and by pressing upon the neck of the bladder, it may prevent the free passage of urine. The prostatic trouble may go farther; the irritation may determine abscess, and the pus may escape by finding its way through the mucous or cutaneous surfaces.

When the prostatic affection does not proceed beyond an increased action of the function of the organ, the patient may complain of a sense of uneasiness or weight in the perineum or in the rectum; but he is oftener disquieted by finding, after the exertion at stool, or in passing the urine, that a certain quantity of viscid transparent fluid passes away also: usually it escapes with the last drops of urine; sometimes with the first. In all cases the patient is tormented with the idea that the fluid is semen.

Usually the medical man has no difficulty in distinguishing between the two. Except the patient be reduced to a state of great exhaustion by disease or by excesses, the seminal fluid is not, like that of the prostate, a perfectly homogeneous and transparent fluid; and usually, by the aid of a microscope, the animalcules, or spermatozoa, may be detected in the fluid which is derived from the testicle. Sometimes, when the prostate has suffered much, the fluid it furnishes will become opaque and less viscid—mucopurulent, in fact; but in that case there will be evidence of prostate disease.

In many cases, then, the discharge which takes place is not spermatic, but prostatic, fluid; but it has exercised an equally depressing effect on the patient's mind. He always believes that the discharge is seminal; and I have always found it very difficult to convince him that it is not so. This discharge happens frequently when the stricture is not very advanced: when the patient goes to stool a certain quantity may pass; so also with the first or the last drops of urine, but unaccompanied with any particular sensation. This fluid is transparent and adhesive, and the quantity passed at a time is rarely great. I have been applied to by patients who had nothing else to complain of; but this was enough to produce profound hypochondriacism. It sometimes induces great debility of the sexual organs; but as I have never known the quantity large, I cannot conceive that the increased action of the prostate can account for it, and therefore I conclude that the debility is mainly dependent on the mental depression.

When the prostate is thus affected, there is only one plan of treatment which I have known to be commonly successful; it is the application of caustic on the prostatic surface of the urethra. How it acts—whether by counter-irritation or otherwise—I am by no means certain; but of the reality of the fact I am quite convinced.

In some cases the irritation determines suppuration of the prostate, when it may be completely broken down and destroyed: the pus may find its way into the bladder or the urethra, or it may make way to the skin.

A man, æt. 62, was under treatment, not long ago, for prostate disease, apparently the result of stricture of the urethra. The account he gave on admission was, at “present no water passed, that for years he had experienced great difficulty in making water, that the water was often thick, that frequently he had severe bearing-down pain in the perineum.” On examining the perineum it was evident that the urethra had given way, and that urine was infiltrated. Several incisions were made; a good deal of purulent fluid with the odour of urine escaped;

fomentations were kept to the parts, and in a few hours he began to pass small quantities of urine by the urethra. The shock he had sustained was, however, too great, and he died. Upon examination after death, the urethra was found not to have given way, but all that remained of the prostate was its fibrous covering; the whole of the secreting structure had been broken down and discharged. The abscess had opened into the bladder, and its contents had no doubt passed away with the urine, but the opening had also admitted urine into the cavity; and hence the state in which we found the perineum.

Still it may be fairly matter of question whether stricture has so much influence as has been frequently ascribed to it in the production of diseased prostate. Like many other organs in the body the prostate has a tendency to undergo change in structure towards the decline of life; that tendency may be made more active in consequence of stricture, but even in the absence of other disease of the urinary organs, the prostate will undergo change: and when it does we have no certain means of controlling it. We content ourselves by giving as free passage as possible for the urine, and attending to the state of the bowels.

Even before the prostate suffers in the way we have described, where the stricture is a close one, if an ejaculation takes place, some of the spermatic fluid is retained behind the contraction, and it then comes away with the urine. But where the stricture is not so close as to prevent the free passage of the seminal fluid, the irritation will sometimes extend along the seminal ducts, even down to the testicle, and will cause either tumefaction of the testicle or a frequent and involuntary discharge of seminal fluid. This discharge happens most frequently at night. I suppose this may be fairly accounted for by assuming that the seminal ducts become distended under this irritation, that during sleep this distension is felt, and that it determines the dream in that particular direction. When this state of things has existed for some time, a partial evacuation of the contents may happen without complete erection. And besides, if the existence of a certain quantity of seminal fluid in the ducts be the stimulus to that orgasm which causes its expulsion, in the end it ceases to be such a stimulus: the openings become relaxed, and the fluid passes off without the orgasm. Lallemand examined a case in which the openings of the ejaculatory ducts would admit a crow-quill.

I have now under my care three patients suffering from the seminal discharges consequent upon the existence of stricture. In one the excretion happens frequently at night,

but the dream under which it is excited is always vividly impressed on his mind. In another the wet shirt is the only indication that it has happened. In the third it escapes during the efforts at stool or in making water; the patient being sensible of a particular feeling which informs him of what is about to happen.

Much suspicion certainly attaches to the nature of some of these cases: when a few drops of a viscid fluid pass only during the efforts at stool, or in making water, in many cases the fluid is not spermatic: if it be examined under the microscope no animalcules are observed in it.

A young man of 19 is at this moment under my care for "seminal discharges." At school, and up to the age of 17, he addicted himself to masturbation. For many months he has had sometimes every night, sometimes twice in a night, what he calls seminal discharges; sometimes he has discharges during the day. He is in good health, fresh coloured, the sexual organs quite natural, no redness about the orifice of the urethra. He is totally unconscious of the occurrence of these discharges during the night. When he awakes in the morning, he finds there has been a discharge; it may have been recent, his skin or his shirt being still wet, or it may have dried up; and there is the evidence. I do not say that the state of his health, and his general appearance, are a proof that they are not seminal discharges, but I can scarcely think that in a young man in rude health seminal discharges can happen under the circumstances I have mentioned, without consciousness on his part. Besides, if it were so, the first urine he passes afterwards should present spermatic animalcules, and in his case they have never been observed.

Some months ago we had an interesting case, shewing the influence of stricture in producing "seminal discharges." A young man presented himself with stricture, which followed upon an obstinate and neglected gonorrhoea. He had been treated twice for his stricture, by dilatation, but he never had patience to continue it so long as was necessary. Twice he had retention, which yielded to leeches and warm bath; still he would not take warning, although he bitterly complained of his disturbed nights from the frequent calls to make water. When he came to us he was much worn by suffering; he complained of uneasiness in the lumbar region, and the urine was turbid. He stated that through the whole of his suffering he had from time to time addicted himself to women; but that for many months the ejaculation was too sudden, and that it was followed by great depression. "At present the erections, when they occur, are very incomplete, and not sustained; the

urine dribbles away; it is thick and ammoniacal, and with it are some drops of a fluid resembling the spermatic fluid; a large viscid deposit takes place from the urine; this the patient conceives to be semen, but I conclude it is bladder mucus made ropy by the ammoniacal condition of the urine. It was evident that the most pressing evil was the state of the urethra; it was equally clear that nothing could be done for the seminal discharge until the canal was made large enough to examine it. As the water dribbled away in sufficient quantity to relieve the distension of the bladder, we determined to use moderate size bougies, and keep them in contact so as to melt down as it were the obstruction which existed. For some time we had little success, but after many attempts we succeeded in passing the obstacle. The jet of urine improved much from this time, and the quality of the urine; the lumbar pain gradually abated. Much uneasiness was still felt about the neck of the bladder, there was some pain in the testicles, there was a muco-purulent discharge, as well as frequent discharges of semen. At this time an attack of hæmoptysis occurred, and he was kept as quiet as possible, nothing being done for the urinary and spermatic trouble but the occasional passage of a bougie. When the chest disturbance became quiet, the urethra, from near the neck of the bladder to the curvature, was smeared with lunar caustic; the application seemed to be rather more than usually painful at the time, but the after sedative effect was very surprising. During the next fortnight there was no one spermatic discharge; but at that time another and more severe attack of hæmoptysis occurred, which carried him off in three days.

Some persons have maintained the opinion that in cases of stricture, under the irritation occasionally set up between the contraction and the neck of the bladder, the openings of the ejaculatory ducts may become blocked up. I never had the proof that such a thing may happen, and I know no one who has. In other secretory organs, one of two things will happen when the excretory duct is blocked up—either the organs shrivel up, and this is rare, or the secretion goes on, the ducts get distended, irritation is set up, and abscess may follow. When is such a state of things observed in the testicle?

When seminal discharges occur in persons who have stricture, whether those discharges have been induced by the stricture, or whether they existed before it was developed, the course to be taken at first is the same—the stricture must be dilated. In these cases you usually see the orifice of the urethra red and tumid; and the patient complains of frequent desire to make water,

of pain in the perineum, and of great discomfort in the rectum. There is also a discharge from the urethra, which is aggravated by apparently very slight causes.

We had in this place not long ago a very good example of the influence of stricture of the urethra in producing mischief in the testicle. The patient was about forty years of age; he had a very close stricture; his urine only dribbled away; and he had a heavy dragging pain extending along the cord into the testicle. After many efforts, we succeeded in passing two strictures, and making the passage tolerably free; but nothing seemed to interfere with the progress of the irritation in the testicle. Fluctuation became manifest; an opening was made, and a quantity of tolerably healthy pus escaped. The urethra by that time was pretty free; but the irritation caused by passing a bougie kept up the discharge from the testicle; we therefore laid aside the bougie for a fortnight, when the discharge ceased, and the sore healed.

Occasionally we are obliged to intermit the use of the bougie because the testicle begins to be painful, even when the stricture is not very bad; and the large instruments sometimes introduced to crush calculi in the bladder are now and then attended by similar consequences, and in such cases the pain is felt to be extending along the cord towards the testicle. In such cases, as the irritation is not continued, the inflammation rarely proceeds to abscess.

In advanced cases of stricture the bladder does not long escape. The contained urine is expelled by a very attenuated stream, and the bladder is not emptied because the contraction cannot be maintained long enough to expel the whole; the desire to make water becomes more and more frequent, but the quantity passed is lessened. The muscular fibres of the bladder, so incessantly called into action, increase in size, and the cavity becomes smaller. The evacuation being at each effort incomplete—the composition of urine undergoing a corresponding change, becoming more and more acid—it irritates the mucous membrane, and induces a secretion from it, which is deposited as the urine cools; and in aggravated cases it may amount to half or two-thirds of the whole of the fluid evacuated, but it does not adhere to the vessel. If the urine be alkaline, the deposit becomes ropy, and clings closely to the containing vessel. You have seen several cases in which the deposit presented this appearance.

After a time the irritation may extend to the ureters and the kidneys. In some cases, in consequence of the constant state of distension of the bladder, the ureters become greatly dilated; the pelvis of the kidney may

participate in this dilatation, and the kidney is not long proof against the consequent irritation. It becomes greatly congested; heavy lumbar pain is experienced; and abscess, or other complication, may be the consequence.

A man died a few days ago, and you had an opportunity of observing those organs after death. He was upwards of 50 years of age, and came in worn down by suffering consequent upon stricture. The desire to make water was frequent; the stream very small; the urine itself turbid. He also complained of uneasiness in the loins. We tried to dilate the canal, and we went on apparently very favourably. The stream increased in size; the desire to pass the urine became less frequent, and the fluid itself improved. His general health underwent a great change for the better. Suddenly he was seized with shivering; we examined the perineum, the loins, and the urine, but could detect nothing to account for it. Diarrhoea came on, but it yielded to ordinary means. He seemed to be shaking off his troubles when head symptoms came on, and he died apparently apoplectic. We found, after death, some, though not extensive, approximation to Bright's kidney, and not much diseased bladder.

Kidney disease, and even comparatively sudden death, are not uncommon consequences of advanced stricture, but the former it is not always easy to detect. In some cases, we may get bloody or purulent urine, shivering, lumbar pain, and fever; in others these signs may be wanting; and in one case which happened to us not long ago, there was no pain in the renal region; there was nothing unnatural in the urine; and yet the abscess which happened in the back was caused by the irritation of calculi which made their way out of the kidney. We have seen other cases in which there was much oppressive pain in the lumbar region, which quickly disappeared when the urethra became free.

In some cases of stricture I have found the urine albuminous, and as the excretion became freer, that fluid also improved. I apprehend, however, that before we can estimate at its proper value the existence of albuminous urine, we ought to make observations on a large scale on healthy persons. I have reason to think that if we took the urine from 100 children reputed healthy, we should find one or two albuminous. It may be said, that though apparently healthy they were not really so. I recollect a patient of Dr. Harrison's who had leucorrhoea, whose urine was carefully collected, but it yielded a larger proportion of albumen than any case I ever knew; yet she went out apparently quite well. I do not for one

moment seek to disparage the value of albuminuria as a sign of disease; but I should be glad to see an extended observation of the urine of persons reputed healthy.

G. H. aged 53, had a stricture of long standing, very unyielding, very close; his urine had been for several years evacuated frequently, but during the greater part of that time never in a continuous stream. For much of that time it had been more watery and paler than natural. Relief had been sought on several occasions, but so soon as the stream of water improved in bulk under dilating instruments, he became careless, and discontinued his attendance. During the previous twelve months there had been occasionally uneasiness in the loins. On two or three occasions for a day or two something like pus had been deposited; it passed with the last drops of urine; latterly, in three instances the urine had been bloody, and it was this feature in the case that gave him alarm, and induced him to give his medical attendant a fairer chance of success. Dilatation was fairly employed, and without any other remedy, under the idea that the suspected kidney disease owed its existence to the contracted urethra, and that if a free passage for the urine were obtained the other discomforts would gradually disappear: the result fully justified the expectation, for as the urethra was enlarged the distress in the kidney region abated, and the patient is now free from any inconvenience in that region.

When stricture of the urethra becomes close, and much exertion is made by the patient to empty the bladder, the effort being frequently repeated, tends to produce a congested state of the viscera of the pelvis, and this is particularly felt in the terminating portion of the rectum. The gut may protrude at each effort, and become very congested, or it may suffer in the shape of piles. In either case the affection is distressing enough; it is no light matter to have the gut descending many times a day, though no difficulty be experienced in returning it; it is a serious evil to have piles tense and bleeding now and again. In such cases it must be evident to you all that no remedy applied directly to the gut itself can avail; you must, if possible, get rid of the necessity of straining at all; and this can only be done by restoring the urethra to its natural diameter. The disease of the gut may have existed so long as to require to be particularly treated; but then it may be devoid of complication, and will yield to treatment which would previously have failed.

MISCELLANEOUS CONTRIBUTIONS TO PATHOLOGY AND THERAPEUTICS.

By JAMES R. SMYTH, M.D. London.

(For the Medical Gazette.)

Rickets—the causes predisposing, exciting, and proximate of the affection—an illustration of morbid etiology in the development of consumption and of typhus fever—rickets and scrofula identical in their causes and natures—this illustrated by cases—treatment of rickets—the plans of treatment of Boerhaave, Sydenham, Van Sweiten, Boyle, some Italian physicians, and others.

THE scientific, and therefore most practical observer of and prescriber for disease, forms, or should do so, his diagnosis *à posteriori*, and his prescription *à priori*; that is to say, from the general assemblage of symptoms and morbid phenomena which in any case present themselves to his observation and judgment, he determines as to the nature and name (if any) of the disorder or disease; and, pursuing his clinical scrutiny and investigation still further, he endeavours to arrive at, and to comprehend, its proximate cause; towards the removal of which he designs and directs his remedies and treatment.

This applies, of course, to the conduct of the well-informed physician or surgeon, more particularly when the object of his therapeutic measures is the effecting of a cure: but when, from the nature of the malady under which the patient labours, such is impossible and impracticable, the aim of his prescriptions and therapeutic expedients, whatever they may be, can only be toward palliation of symptoms, and more or less improvement of condition; or perhaps to lighten and appease the last painful stage of life's weary journey and approach to "the undiscovered country from whose bourn no traveller returns."

Morbid etiology generally, and properly, resolves itself into three kinds of causes, namely, *predisposing, exciting, and proximate*. This division might appear somewhat refined and artificial, but such is not the case, as it unquestionably has its full existence in fact. Let us adduce an example in illustration of the entity and too frequent mode of operation of these three causes; and we will choose the case of one of the many delicate and interesting—in some instances, indeed, too interesting, because too delicate—young ladies who constitute the beauty, life, and joy, and attractive captivating ornament and charm of society, in all its variety of better relations in this great metropolis, and every where else. We will choose, we say,

the case of one of these young ladies, destined, through hereditary consumptive diathesis, and the changeable ungenial nature of this northern climate, aided by erroneous unhealthy educational and social arrangements and customs, to fall, like some tender early flower nipped by cold, a victim to the malady of phthisis. The hereditary diathesis, or specifically ill developed and organised state of the fluids and solids, then, in such instance, forms the predisposing cause, the ungenial atmospheric agency the exciting cause, and the tubercular matter deposited in the lung the proximate, sustaining, or constituting cause. Or, let us take a case somewhat different, but one equally in point, that of the outbreak and spread of typhus and contagious fever in a population suffering from insufficient or unwholesome food, and other not unfrequently accompanying privations. The diminution and defect in the quantity of the blood, with its impoverished vitiated qualities and condition, and the concomitant resulting depression and debility of the circulation, and of the entire economy, form here the predisposing cause. And, under such circumstances of predisposition, an unusually severe impression of cold, the more than ordinary exhaustion and fatigue consequent upon a toilsome day's labour, or more or less unusual privation of diet or sleep, or some event which gives a depressing shock to the mind and spirits, or, when the fever proceeds from contagion, the reception of the animal or vegetable *miasm* into the circulating fluids and system, and its impression and injurious effects thereon, form the exciting cause; the peculiar, perhaps specific, morbid change and derangement of its vital affinities and constitution which the blood undergoes, and which originate and continue the febrile state and phenomena, form the proximate or sustaining cause. "That," truly and elegantly observes Van Sweiten, "is called the proximate cause of a disease which directly constitutes the whole present disorders, the presence whereof founds and continues the disease, and the absence of which removes it."

In the etiological pathology of rickets, the predisposing causes of the malady, like those of scrofula and consumption, are chiefly referrible to hereditary taint and organisation. When, as sometimes is the case, the disease becomes developed in the system of the child, not the offspring of strumous or otherwise debilitated parents, it is difficult, and, indeed, unnecessary and useless, we think, to draw any distinction between the predisposing and exciting causes, as these are, in fact, the same morbid agents, which would appear to differ only as to the times and greater or less intensity of their mischievous actions. When a congenital strumous and rickety diathesis exists, a shorter and less rigorous operation

on the infantile system of those causes which ordinarily act as the excitants of the disease, which we shall presently enumerate, are sufficient to quicken the malady into life and form.

And, on the contrary, where such diathesis or physical predisposition does not exist, but when the affection, like an isolated case of typhus fever, is altogether the offspring of contingent and external circumstances, a longer and more severe operation of those morbid agents are, generally speaking, requisite for the production of the disease.

That scrofula and rickets are, as we have already observed, distempers identical in nature, though somewhat different in their symptoms and forms, there cannot, we conceive, be a doubt; and that a scrofulous condition of the economy in either parent may, and does, according to modifying circumstances, act as a cause either of a like malady—that is, of scrofula properly so recognised, or of rickets in their offspring—there is sufficient evidence to verify. We have witnessed in the family of a respectable artisan, the father of ordinary stature, of active constitution, and free from every kind of debility and disease; the mother of large person and leucophlegmatic temperament and form, with tendency to a strumous state of the lymphatic glands generally, but without any particular scrofulous ulcer or tumor; one son, thirteen years of age, who inherited the temperament and constitution of the father, robust and in every respect healthy; another son, between eight and ten years old, the subject of severe scrofulous diathesis and debility and scrofulous enlargement and ulceration of the submaxillary glands, and also of the lymphatic glands on the side of the neck; an only daughter, fourteen, stunted in growth both of body and mind, of large head and abdomen, of bowed legs and arms, and twisted deformed spine and pelvis, of soft infantile flesh, and stupid lax countenance; in short, an unquestionable example, in every symptom, of the malady of rickets. There would appear to be a great defect in the power of developing animal heat in rickety individuals. This dwarfed and deformed creature, although she could walk and run in a straddling unsteady manner, generally sat, like some stray and disabled eld, during the autumn and winter, the vigilant guardian of its own hearth, and the warmer and brighter the fire the more pleased and animated it seemed to be. We have witnessed again, in one family, the father the subject of scrofulous enlargement and ulceration of the ankle-joint, and bones of the tarsus, a son, nearly arrived at the age of manhood, labouring under scrofulous necrosis of the lower third of the femur, and also of the middle third of the connected tibia; one daughter, beyond twenty, strong and healthy; another daughter, between a year and two

years younger, rickety, and curved and deformed in various ways. The mother died of ovarian dropsy, resulting from serofulous disease of the ovarian bodies. In a medical controversy, upon perfect and imperfect rickets, held at Strasburgh ninety years ago, or a little less, by Buekner, that celebrated author adduced the case of a female of the labouring class, the subject of “king’s evil,” scrofula, who was mother of eleven rickety children, all begotten by the same father, a man remarkably healthy both before and during the time his family was increasing. Boerhaave, in one of his aphorisms, treating of the etiology of rickets, states to the following effect, and nearly in the same words: this disease is chiefly fatal to children whose parents are of a lax weakly constitution, are indolent and delicate, who live luxuriously, who eat little bread, drink sweet wines, and much warm water; who have been exhausted by chronic diseases, generative intemperance, age, and particularly if they have had the lues venerea and frequent gonorrhoeas, for such generally propagate a weak and languid offspring.

Although such pathological doctrine is not, we believe, generally taught, repeated attacks of gonorrhoea and long-continued gleans have certainly the effect, in not a few instances, particularly in the male, of greatly depressing the spirits, and of relaxing and softening the solids, and also of weakening in no inconsiderable degree, temporarily or permanently, the entire system and constitution. The offspring of an individual labouring under such debility of system is very likely, no doubt, to be weak, and disposed to disease, and most of all to the distemper of scrofula in some of its different forms. In some constitutions that have experienced repeated attacks of gonorrhoea terminating in lingering gleans, the hair loses its softness and healthy appearance, and becomes dry and falls off. We have ourselves witnessed two cases of this peculiar depilation; a symptom, we conceive, of profound constitutional injury. In one of the cases there was also falling off of the eyebrows, with disfiguring permanent dwarfish regrowth of the parts. Dr. Macartney, the late Professor of Anatomy and Surgery in the University of Dublin, one of our most acute observers, and a profoundly learned physiologist and pathologist, was accustomed, we believe, occasionally to direct the attention of his numerous pupils to this remarkable fact.

The causes from which the malady of rickets is generally considered immediately to derive its existence, and by which, whether with or without a predisposition in the economy, the *essentia morbi* and its external characters are generated (if we may use the term) and developed, and in consequence of

which they are denominated its exciting causes, are referrible, chiefly or altogether, to the condition and circumstances of the child as regards aliment, air and exercise, habitation and clothing, and exposure to wet, damp, or cold.

In every case of rickets which has come under our observation, the system of the individual certainly had been, or was being, subjected to the unsalutary agency of insufficient and unwholesome nutriment, in the form of breast-milk, or food artificially prepared; its habitation was generally damp, cold, and confined, and excluded in a greater or less degree from the due influence of the sun; the nursing and physical education of the child was negligent and bad, it being seldom in the free insolated air, and sometimes but scantily clothed. The following observations on the etiology of rickets, which we extract from the article on this malady in the *Dictionnaire de Médecine*, are, we consider, so sound and excellent, that we cannot do better than give them a place here:—
 “*Laissant donc de côté les hypothèses, pour ne nous arrêter qu’aux faits, nous avouerons franchement que la cause du rachitisme nous paraît totalement inconnue. Le principe de cette maladie se développe spontanément chez certains individus qui y sont plus disposés que d’autres par leur constitution. C’est ainsi qu’on voit souvent tous les enfans d’une même famille devenir rachitiques, que cette maladie se transmet à une ou deux générations, et que cette disposition héréditaire s’affaiblit, soit par le croisement des races, soit par le changement de régime ou d’habitation. Pour les individus chez lesquels cette disposition primitive est cachée et existe déjà, plusieurs causes secondaires peuvent concourir à développer la maladie: ainsi le travail de la dentition, l’affaiblissement de la constitution à la suite de plusieurs maladies aiguës et chroniques, deviennent autant de causes occasionnelles de rachitisme. L’habitation dans des pays humides paraît aussi favoriser le développement de cette maladie. C’est principalement en Hollande, dans le nord de la France et en Angleterre, qu’on l’observe plus fréquemment. Elle était tellement répandue dans ce pays, vers le courant du seizième siècle, qu’on lui avait donné pendant un certain temps le nom de mal Anglais; c’est surtout dans les grandes villes les plus peuplées, à Londres, à Amsterdam, à Paris, que le rachitisme s’observe plus fréquemment; il est plus rare dans les campagnes, dans les bourgs, que dans les grandes villes. Un mauvais régime alimentaire paraît contribuer à favoriser son développement. Les enfans de la classe inférieure, qui sont très-mal nourris dans les grandes villes, y sont en general plus*

sujets que ceux de classes élevées, quoique ceux-ci n’en soient point exempts.”

“Leaving aside, then, hypotheses, to confine ourselves to facts, we frankly avow that the cause of rickets appears totally unknown to us. The seed of the malady is spontaneously developed with certain individuals, who are more disposed to it by their constitutions. Thus it is that we often see all the children of the same family become rickety, and this malady transmit itself to one or two generations, and again this hereditary disposition becoming weakened either by intermarriages or by change of regimen or habitation. With those individuals in whom the primitive disposition is concealed, and still exists, many secondary causes may concur to develop the malady; thus the pain and disturbance of dentition, the constitutional debility consequent upon many acute and chronic diseases, become as many occasional causes of rickets. Habitation in damp countries appears also to favour the development of this malady. It is chiefly in Holland, in the north of France, and in England, that we observe it most frequently. It was so prevalent in this latter country during, or towards the end of the sixteenth century, that, for a certain time, they had given to it the name of the English disease. It is principally in the great and most populous cities, such as London, Amsterdam, and Paris, that rickets is observed most frequently. It is more rare in the country and towns than in the great cities. Unwholesome aliment appears to favour its development. The children of the poor, in the great cities, who are very badly nourished, are in general more subject to the disease than those of the higher classes, although these are not exempt.”

The damp and cold, and other atmospheric agencies of marshy and maratine localities, are considered by many to operate with peculiar effect as exciting causes of rickets. The disease was very prevalent at one time in Halle, in Saxony, owing, it was thought, to the very moist and unhealthy state of the atmosphere of the town, resulting from saline and carbonaceous exhalations suspended in it. Like some other maladies which occasionally exhibit an endemic character, rickets has been viewed as a disease caused by, and propagated by, contagion; but such an opinion we do not consider to have any foundation in fact. Sydenham has observed that the rickets—“true rickets*,” to quote his own distinction,—was most common, in his day, in those seasons in which autumnal inter-

* Sydenham, it would appear, made out two sorts of rickets—one true, the other false. The latter, we apprehend, was nothing but infantile atrophy, with mesenteric or some other abdominal disease.

mittents prevailed; and it would seem that he was disposed to consider the intermittent fever as the originator, in a great degree, of the rickets.

It is difficult to determine respecting the proximate cause of rickets. The blood and humours in this disease, it is certain, early discover deterioration of their qualities and constitution. But the blood and circulating fluids generally—are they not, let us ask, at all times chiefly dependent for their existence, and the conditions of the same, healthy or unhealthy, on the functions and operations of the chylopoietic viscera and other organization of digestion? No question but such is the case. "During the whole course of this disease," observes Boerhaave in one of his aphorisms, "a slow fever consumes the body until death; and then all the fibres, membranes, vessels, and viscera, appear soft and flaccid, the humours dissolved; so that we may conclude the proximate cause of this disease to be a sluggish, cold, and vapid cacochymy, together with a very loose structure of the solid parts." To this doctrine of the proximate cause of rickets Van Sweiten also gave his approval; and Du Verney, Buchner, and others, state that the blood of rickety children is dissolved, thin, and watery, and the flesh greatly decoloured.

Some authors, it is but proper here to state, as Bonetus, the learned Heister, Glisson, and others, have asserted that the medulla oblongata, in rickety subjects, is found to be unusually hard, and apparently obstructed; from which circumstance the proximate cause of the disease has, by some, been placed in impediment to the free passage of the nervous fluid or cerebral influence into the spinal marrow, and thence into the trunk and extremities.

Treatment.—The first thing to be done in the treatment of this disease, or indeed in that of any other, is to rid, if possible, without delay, the individual from the influence and operation of its exciting causes. Though these, in the malady under consideration, may, as we find they do, according to circumstances, vary in degree of action and morbid effect, and though they may therefore, in some manner, modify and vary the external phenomena of rickets, the distemper is, however, we believe, essentially a disorder of infantile digestion and general nutritive and organic assimilation. If lingering feverishness and debility, with symptoms of rickets, such as we have described in a former paper, begin to show themselves in a child while at the breast, the health of the wet nurse should be immediately inquired into, and her milk examined, and, if not found wholesome and nutritious, a new nurse ought to be provided for the child, who might afford it the necessary

salutary aliment*. Without question, every infant, with a few rare exceptions, should be gradually weaned as soon as it has attained the age of nine months, as suckling it, and encouraging it to subsist altogether or principally on fluid nourishment after that period, is more a cause of physical relaxation and debility than of tone and strength to its digestive economy and constitution. Protracted suckling, in fact, is looked upon by many, and with some reason we think, as a frequent cause of rickets. We are undoubtedly too frequently in the habit of neglecting the sound and certain dictates of nature. The child, every one knows, usually begins to cut its teeth when it is seven months old; and the object, plainly enough, of the development of the teeth is to furnish the little aspirant for man or womanhood with instruments for the mastication of more solid food, which should be presented to it, in more or less quantity, as soon as the teeth have made their appearance. If dentition happen to be difficult, and thereby prove a source of pain and irritation, and of disturbance of the child's digestion and health generally, the protrusion of the teeth should be facilitated by incision of the gums.

In the early and acute stage of rickets, when the febrile symptoms are considerable, and we have acceleration and resistance of pulse, with fretfulness and anorexia, and dryness, or tendency to dryness, of the skin, with more or less disorder of the alvine and urinary excretions, some hepatic alterative aperients, consisting of calomel or hydragryrum cum cretâ, with rhubarb, in the form of a powder, and a mixture composed principally of compound infusion of senna, with carbonate of soda and sulphate of potash, together with antimonials and the tepid bath, should be administered, and repeated as indications might prompt. The object, let us state, of the mercurial and alkaline medicines here advised is to urge and render active the biliary secretions, and emulge the liver, which viscus, we apprehend, is, to a greater or less extent, implicated in the etiological pathology of rickets, and, as we have seen, is liable, in an early or late stage of the disease, to become, in a greater or less degree, congested and enlarged.

With increased bulk of the head, when symptoms of cerebral excitement and cerebral congestion and oppression are present and

* "Milk contains only one nitrogenised constituent, known under the name of *caseine*; besides this, its chief ingredients are butter (fat), and sugar of milk. The blood of the young animal, its muscular fibre, cellular tissue, nervous matter, and bones, must have derived their origin from the nitrogenised constituent of milk, the caseine; for butter and sugar of milk contain no nitrogen." (Liebig's *Animal Chemistry*, second edition, page 51.)

urgent, a cold lotion ought to be constantly applied to the head, and one or two leeches, or perhaps more, as symptoms might suggest, should be applied to the forehead, or to the temples, or post-aural regions. In the time of Glisson, scarification of the ears, indeed, was a remedy much relied on, and generally practised, in this country in the treatment of rickets; no cure of the disease, it is said, being confidently expected without its adoption. As soon as the symptoms of febrile excitement, and of cerebral² disturbance, have somewhat subsided, and the derangement of the digestive functions has been put in some degree to right, and the malady is beginning to assume a chronic character, the child ought to have daily, with its other diet, milk, or whatever it may be, animal nutriment, properly prepared, and in quantity suited to its age, and its digestive powers. Change of habitation is also very requisite. If a rickety child, as too many of them are so situated, be living in a damp, cold, secluded, ill-aired, and worse lighted place in town, or in a low, unhealthy locality in the country, it should be removed to a residence affording hygienic conditions and influences different and more salubrious; and, being warmly clothed, and carried in an easy position in the nurse's arms, or in a carriage, it ought to be as much as possible, when the weather might permit, in the open sunny air. It is a custom (which experience of its good results has no doubt rendered customary) in some parts of the continent, with parents who have rickety children, to expose them frequently to the warm sun, on dry sandy eminences, in fine spring weather. There is, it is certain, no immediate cure, and but little amendment, whatever medicinal remedies we may prescribe, to be expected for the child labouring under the cachectic chronic disease of rickets, so long as it is kept cooped up within doors, and fed principally on sloppy vegetable and farinaceous aliment; it ought to have air and exercise daily immediately after breakfast, and again after an early dinner, between 1 and 2 o'clock, when cold or rain did not forbid, and animal food of the younger sort, the best of its kind—beef or mutton, or veal or fowl, or ham, plainly cooked, in moderate quantity, twice a day. During the employment of these remedial dietetics, it may also be necessary to keep the intestinal canal, and its functionally associated glandular viscera, the liver in particular, gently active for a time, by means of some alterative aperient, administered daily or every other day, according as the condition of the alvine excretions might suggest; which it may also not unfrequently be found beneficial and contributive to the cure, to follow, by the use, twice a day, in small rather than in large doses, of some chalybeate medicine, the carbonas ferri,

or the tinctura ferri muriatis, or the vinum ferri, for instance. The following is the substance of the therapeutics for the treatment and cure of rickets of the celebrated Herman Boerhaave:—The malady of rickets is best cured by a light, dry, diet of animal food, not fat, of easy digestion, and seasoned with the mildest spices, given often, but in small quantity; by generous liquors, drank in moderation, especially fresh beer well brewed; by a dry and warm air, and warm clothing; by sleeping upon mattresses filled with aromatic strengthening herbs, placed in the highest and driest apartment in the house; by tossing, shaking, swinging and dancing them, and by having them borne in a carriage over stony rough ways; by repeated warm dry frictions with flannel impregnated with the smoke of aromatic gums, principally applied to the abdomen and spine; by gentle emetics given with caution; by purging for some days successively with rhubarb, or some other aromatic cathartic; and lastly, by a long-continued use of strengthening and cordial medicines. The cold bath and liniment are also mentioned, but without experience as to their effects.

In the treatment of rickets, Sydenham appears to have placed his confidence chiefly in purgation. "According to the age of the child," observes Sydenham, "give it a spoonful or two, more or less, of the purging potion above set down* every morning for nine days, intermitting a day or two, if need be; and the purgative must be so proportioned, either by increasing or diminishing the dose, as to give but five or six motions a day. When the course of purging is over, let the abdomen be anointed with an opening liniment for some days. By this method I have cured several children of the true rickets."—(Sydenham's Works, by Swan, page 64.)

Several medicines of chalybeate and other natures have held considerable repute for a time, and have had the confidence of eminent individuals both in this country and on the continent, as agents exercising a specific control over rickets. The great and philosophic Robert Boyle introduced as a specific against this malady the now antiquated medicine known by the name of *ens veneris*†.

* The following is the prescription for the purgative potion here referred to, which was the same also that our English Hippocrates was in the habit of administering to his patients in continued fever:—

Infusi Senna, Infusi Rhei, aa. oz. iss.; Tamarindi Indica, oz. ss.; Manna, Syrupi Rosæ, aa. oz. j.; M. ft. mistura.

† There has been some difference of opinion amongst pharmacutists and others respecting the true nature of *ens veneris*. Some will have it that it was a preparation of copper, others of iron. We are of opinion that it was a preparation of iron, the *perchloride*, which is not, we believe, amongst the medicines of any of our pharmacopœias.

"Partly by a sister of mine, to whom I communicated it, and partly by myself, and those I directed to take or to give it, I think I may safely say," states Boyle, "that two or three hundred children have been cured by it, and that almost always without the help of any other inward medicine, or using any topical application at all." (Boyle's Works, vol. v. p. 121.) The usual dose was two or three grains (which could be increased to thirty without any ill effects) given in distilled water, small beer, or any convenient vehicle. Van Sweiten observes, that when this remedy caused a sensible increase of perspiration, and of urine, it operated as a certain specific against the rickets. Benevoli, also, has given his testimony to the beneficial effects of *ens veneris* in rickets; and in proof of the same, has related, in his writings, several cases of cure produced by it, one of which, indeed, we quoted at length in our last paper. Van Sweiten speaks in high terms of the good results he has witnessed from "golden tincture of steel" (muriated tincture of iron of the modern school of pharmacy) administered as a remedy for rickets. He states that he cured numbers of rickety children by feeding them on biscuits and mellow generous beer, and giving them, at the same time, three or four drops of this tincture twice a day in a little wine. Zaviani used the same remedy for rickets; and so, also, did Benevoli, who administered it in milk. De Haen gave the *ostracodermata* (of Aristotle) in fine powder, in scruple doses, two or three times a day; and he states that if the rickety children using this medicine enjoyed the benefit of a warm sun in the country, of exercise in a child's coach frequently during the day, and of a dry bed and chamber, with sound aliment, they were soon cured. Hemlock and madder, too, have had their commendations as remedies for rickets. We find cases related by writers on this malady, in which the former of these medicines was given to young children to the amount of four and six grains a day, with, as they state, the best results. We do not ourselves, we confess, put any confidence in hemlock or madder as remedies for rickets.

It is better, we believe, while the bones of rickety children are soft and liable to contract curves and deformities by efforts at standing and locomotion, to confine these little patients as much as possible to the horizontal position, as well while they are being borne about in the nurse's arms, or in carriages, as when they are in bed. But with all the care by the most careful, in this respect, that may be taken of rickety individuals, it is perhaps impossible, in many cases, to prevent some of the long bones, and the chain of vertebrae of the spinal column, from becoming morbidly bent and deformed. Wherever there is any considerable degree of

rickety or scrofulous taint, with its peculiar accompanying debility in the system of the infant, or young growing individual, it seldom fails to manifest itself by some kind of curvature or deformity of the spinal column. It is certainly the bounden and imperative duty of every parent or other responsible person to whom the care and welfare of weak and rickety children are entrusted, to do all in their power in every way to prevent them from becoming deformed, and disabled, and distorted pitiful objects, often disagreeable and painful to behold, as many of them we almost daily see about the streets and lanes of this city are. And we will observe, that, for such purpose, in aid to the medicinal treatment, we are not disinclined to think but that benefit and assistance, sometimes considerable, may be derived from the judicious application of mechanical means, which, it is scarcely necessary to remark, is more the part of the surgeon than of the physician to devise and apply. If not trespassing on the field of the veterinary physician, before concluding for the present the subject of rickets, we will remark, that this malady, like that of scrofula, is not one exclusively confined to the human species; some of the inferior animals are also liable to be attacked by it. The disease may occur in the monkey, lion, horse, ox, and in the sheep, pig, and dog, more particularly the pointer and greyhound, and also in geese and ducks. We have ourselves seen the disease of rickets in the terrier, the turkey, and peafowl.

We intend, in our next paper, to resume the subjects of impotence and sterility, and to continue them, without interruption, till terminated; and we hope to be able to place before the profession and the public some facts and cases deserving of their attention and consideration.

43, Sackville Street, Nov. 30, 1843.

REMARKS ON THE IMPUNITY OF CERTAIN ATTEMPTS TO MURDER,

By T. MAYO, M.D.

Fellow of the College of Physicians, and Physician to the Marylebone Infirmary.

[Concluded from page 305.]

I HAVE endeavoured in the above reasoning to obtain points of distinction, which may enable us to apply to the defence of mankind against injurious acts performed by the insane, that power which the insane are known to possess under certain limitations,

and in certain kinds, of controlling, from prudential or other motives, their own tendencies; that power which, under the improved management of the present age, is so often employed for their benefit, and often for their cure; and which in these instances might be exhibited in so far limiting their delusions as to render them compatible with the peace of society. Occasional difficulties must arise in regard to this as well as to every other class of offenders, in applying penal principles. General rules must occasionally apply a pressure too stringent at some point. But in this case, it must be remembered that the interests of the insane are as deeply involved as those of the public. It is, indeed, a most oppressive infliction, though one by no means preventive, because it does not come in the shape of a punishment, which the insane incur under our present system. We wait, for instance, until they have committed some murderous act, and then inclose them in a madhouse for life. (See Appendix, No. 3, p. 336.) Had the friends of Macnaghten viewed him as liable to a *penal* infliction, in case of an outbreak against society, of which he seems to have given them ample notice, it is reasonable to presume that some means of cure or prevention might have been resorted to by them.

In Macnaghten's character murder was probably, in some sort, as Dr. Monro termed it, the crowning point or climax to which his delusion tended. In a milder or more kindly character, the blood of the offending party would not have been pointed to as requisite, or the requisition would not have been listened to. Again, had insanity occupied the whole character and conduct of Macnaghten in relation to his fatal act, a circumstance practically disproved by his deliberateness, he would have afforded no preventive example to others by his punishment, and that punishment would have been gratuitous. Such as he was, had punishment been awarded to him, he would have afforded an invaluable example to thousands of ill-regulated minds, in which a seed of insanity springs to life in a hot-bed of evil passions, or wayward dispositions, or over-stimulated imagination (See Appendix, No. 4, p. 336), while the impunity accorded to the name insanity places at the dis-

posal of their passions the means of their gratification. It is in this way that Sir Walter Scott exhibits the effect of a false perception on the feverish and impassioned character of Allan Macaulay*. Could it have been possible that the peeps into futurity with which the good Emanuel Swedenborg indulged *his* imagination, should have armed *his* hand against the friend of his heart?

The dangerous effect on the insane of allowing them to consider insanity a ground of exculpation, under whatever circumstances it may be pleaded, has been illustrated by a reference to a conversation between the patients of an establishment near York, in which they were overheard declaring, that Martin the incendiary would not suffer any penal consequences from his act, because (they said) "he is one of us." To the argument in favour of the punishment of insane persons, founded on this fact, it has been replied, that the insane are, as such, unaware of their own state, and consequently will not be influenced by the escape or punishment of other insane persons. And this reply would be a good one, if its assumption were correct, that they contemplate the other persons as insane. But this assumption is erroneous. Those whom they recognise as actuated by motives and views similar to their own, they regard equally with themselves as of sound mind, and only (as an insane lady once described herself to me, when I was pointing out the deviations of her conduct) "in a minority."

The reference of insanity to conduct varies in relation to the mind in which it occurs, and the extent to which it has influenced a given mind. In some persons it spreads, as it were, through every fibre of the character; in others it taints the character with erroneous impressions, but leaves the agent free to deal with these impressions, in regard to the conduct which they suggest, according to the general construction of his mind, and the extent to which they are antagonised.

In the case of Bellingham, affidavits were put in, stating that if more time† had been given before his trial, evidence establishing some features of

* Legend of Montrose.

† Bellingham's crime was committed on the 12th of May; he was tried on the 15th.

monomania would have been obtained. In this case Bellingham would probably have escaped, though, on the grounds on which *we* would have awarded punishment to Macnaghten, obviously deserving it.

In the murder of Mr. and Mrs. Bonar, at Chislehurst, the confession of Nicholson, evidently made with no purpose of trumping up a story of lunacy, bore strongly the character of an attack of homicidal monomania; and had not this supposition depended entirely upon a statement made by himself, it is very probable that circumstances confirmatory of it would have been sought out; in which case the murderous villain, if assisted by able counsel, would possibly have escaped into a madhouse, and an important preventive example have been removed from the public eye.

There were points of eccentricity in the character of Lord Ferrars, which, in the present day, would have made his chance of escape a very good one. Lord Ferrars was, in truth, of unsound mind; but his unsoundness belonged to a species of that great genus (a species distinct from insanity), which ought to confer no immunity from punishment. He was eminently and exquisitely a brutal character (See Appendix, No. 5, p 336), as described in the work to which this essay is supplementary—a man without a moral sense: fear could alone have controlled him; and it was evident that his intellectual powers were sufficiently vigorous and clear to have estimated the nature and chances of punishment, and to have contrasted it with the pleasure of gratified revenge.

Macnaghten himself expressed, in a conversation between him and his medical advisers, which my friend Mr. Maclure reported at the Harveian Society, that he should not have “liked to be hanged for his attempt on Mr. Drummond’s life.” But he also said, that he felt sure that the Duke of Wellington would not hang him. In fact, the strong indisposition evidenced in the present day to inflict capital punishments, and the uncertainty thus produced, give to many offenders a dangerous reliance on escape.

Some very mischievous escapes have taken place under the vagueness of our law in its application to this subject. It has, indeed, been penal or exculpa-

tory just as the case might chance to influence the sensibilities or the reason of the jury or magistrate. The impunity of the officer who attempted to assassinate Lord Palmerston is one of these cases. And such also was the case of Miss Broadrick, who murdered Mr. Errington. In drawing a distinction between her case and that of Hadfield, Mr. Erskine very justly argued, that Miss Broadrick acted in reference to circumstances which had a real existence, as well as under the influence of those passions and motives which are naturally excited by such circumstances. He saw no connection between her case and insanity; and was of opinion that she ought not to have been acquitted. In the Annual Register of 1795, in the report of that case, Chief Baron Macdonald, before whom it was tried, is noticed as having considered the laughter of Miss Broadrick, after her commission of the horrid deed, as an evidence of insanity, and to have charged the jury to that effect. “Moody madness” is indeed described by the poet as “laughing wild amid severest woe;” but the Chief Baron should have considered that these latter expressions scarcely describe the state of feeling produced in an ill-regulated mind by gratified revenge. Miss Broadrick had punished the man by whom she had been deserted, in the presence of her for whom she had been deserted—a very sane procedure, though a very shocking one.

Assuredly the case of Oxford would also find a place in the above number. This young man was plainly capable of appreciating his own offence in relation to the laws of his country, and his general knowledge of right and wrong was equal to that which we have attributed to the felon, whose case we supposed at the commencement of this essay. His punishment would have acted most beneficially on the fears of others. Whether in favour of the weak-minded, whose acts are not characterized by sufficient deliberation to entitle them to the awful punishment of death, some other punishment might not be devised of greater preventive efficacy, as being, from its less severity, of more certain application, is an important question. The *entire* escape of Oxford was confessedly most mischievous.

That the extracting grounds and

motives for penal measures out of a theory of desert and moral responsibility, or, in other words, of justice, is unattainable by human legislation in any class of offences, has already been noticed. But this matter deserves to be reconsidered. Justice, in its sense of securing to every man his due, may be considered in two great relations; either as regulating the dealings of mankind with each other, or as correcting the offences which they commit against each other. In the first of these relations, the abstract theory of justice, the giving every man his due, is carried out, or nearly so, in practice. In its second relation, with the present endowments of the human mind, the realisation of justice in our practice is not equally easy. Some aids it no doubt possesses in the construction of our minds. The feeling of indignant emotion was no doubt imparted to us as a guide towards punishment, viewed as an act of justice. Still the appreciation of the grounds on which, and the extent to which, that feeling may act, is vague indeed, in comparison with the precision with which the contracts and exchanges of distributive justice are carried on. Man was made to live with his neighbour, not to punish him. But the account of our misdeeds cannot be carried over entirely to another state of being. We are compelled to inflict punishment, and compelled to do this on a principle, mainly, of prevention; still, in doing this, we anxiously crave the nearest possible approximation to a principle of justice, and desire that although prevention must be the immediate motive of penal inflictions, a theory of desert should be the measure of their severity; inasmuch that the preventive force of punishment will be greatly increased in proportion to the extent to which the admeasurement of the punishment gratifies this appetite, and avoids the semblance of injustice.* Indeed, unless this precaution is used in the admeasurement of punishment, it will be-

come a dead letter. The sympathies of mankind will resist its enforcement. The extent to which an amended consideration of the subject might in some cases mitigate punishment, without doing it away entirely, is not at present before us. The valuable act, passed July 1842, for the further defence of Her Majesty's person, may be considered an instalment towards this kind of legislation. For it was produced by the delinquency of a wretched boy, whose presumed unsoundness of mind protected him against the operation of those existing laws to which his act was *primâ facie* obnoxious. The place into which the lunatic criminal is received after conviction should not in a general way be that in which the innocent lunatic is detained; it may very fitly take the name, and some of the habits, of a prison. This would be a fair opening in this class of cases for what Mackintosh calls reformatory punishment.

I am not advocating severity of punishment, but merely demanding that the consequences of offences against the community committed by the insane, when the punishment *primâ facie* awarded by law appears unfit, as revolting to our sense of justice, may in certain cases assume to them the character of a punishment in some form or other;* and not be wasted, as at present, in unproductive suffering. Let it, indeed, be remembered, that the treating them in all respects, as far as possible, on the same principles with rational beings, as subject to motives and capable of being influenced through hopes and fears, is good for them, as well as for society at large; though actions some way connected with delusions *may* thus be made the subjects of punishment. Under an opposite system they will still receive, with a different name, a very heavy punishment. Thus, a partially insane person, incarcerated in a mad-house for life on account of a murderous act springing out of his delusions, is actually in a very wretched plight. His state has all the attributes of a most bitter punishment, except those which tend to prevent a repetition of the offence in others. Soon,

* This concession in favour of the introduction of other objects, besides prevention, as recognized by law, is more than that truly humane philosopher, Sir James Mackintosh, demands. "The object of law," he says, "is the prevention of actions injurious to the community. It considers the dispositions from which they flow only indirectly, to ascertain the likelihood of their recurrence, and then to determine the necessity of means for preventing them."—*Ethical Philosophy*.

* See Appendix, No. 6, p. 337.—A brief statement of a case tried on the 31st of October last, before Mr. Justice Maule and Mr. Justice Wightman, will there be found, which forcibly illustrates these views.

indeed, he is shut out from the thoughts and recollections of man; or, if recollected by those who ought to profit by his sufferings, he is only recollected as one who has plenty to eat and drink, and nothing to do!

Unless the perverse rhetoric of the philanthropist should occasion a reaction of public feeling in an opposite direction to that which they advocate, there is no danger that penal measures should be carried out against the insane with undue harshness, in the present day.

I have thus endeavoured to ascertain the principle on which the plea of mental unsoundness may be applied in exculpation of criminal acts. The practical questions which I suggest on this subject are, first, whether the insane offender is aware at the time of commission of the nature of his act in reference to law; secondly, whether, though aware of the state of the case in this respect, he is in a condition to be withholden by that knowledge from the offence.

The first question answered in the negative will at once place him out of the reach of punishment.

In estimating the second question, in each case as it arises, I assume the same ultimate grounds of exculpation as under the first question. In each a state of present insanity, connected with the criminal act, and rendering the threat of punishment inoperative, constitutes the plea in behalf of the offender.

I have endeavoured further to point out that although a bare perception of preventiveness or non-preventiveness in punishments proposed must be the basis and motive of our legislation on the subject, no violation of our rational and manly sympathies is hereby suggested. No doubt difficulties must be felt in applying the distinctions and limitations required. But is this application impossible? Is not this very difficulty connected with a certain faultiness in our judicial arrangements, which seems to leave the subtle question of mental unsoundness, as determined by law in its relation to crime, at the disposition not of judges, but of jurymen? At all events the case demands an effort; "*anceps remedium, melius est quam nullum.*" As the matter stands at present, the great, the

good, the high placed, also, who in this country are likely to belong to the first two classes, are placed, under causes often connected with their very merits, in direct exposure to the knife of privileged assassins.

Before I quit this subject, I may make some remarks upon a part of it which immediately concerns the interests of our profession, but which has, in truth, great *public* interest. Subsequently to the trial of Macnaghten, many strictures have been passed on the judicial influence exercised by the professional opinions given on that trial. Medical practitioners are at present in an embarrassing position in regard to this subject. It constantly occurs to them to find their opinions solicited and implicitly accepted, not only in their *proper* province, the *pathology* of the case, but also as to the application of the penalties of the law to the acts which spring out of it. Thus, the Chief Justice stopped the trial of Macnaghten, because all the medical men concurred in opinion, not only that he was mad, which was the point to the extent of which they ought to have been consulted, but also that he was an "irresponsible agent," by which they meant a person not liable to punishment, a consideration no doubt having many relations to the question of madness, but still distinct. Now, defective as our law at present is, had the Chief Justice tested the opinions of those medical witnesses by the legal criterion offered in the opening speech of the Attorney General, he would have placed the medical witnesses in their right position, and possibly have himself arrived at a different conclusion. But he was contented to allow them to supply him with law as well as medicine. If the dicta of the earlier English lawyers on this subject are (justly) considered inapplicable, let them be displaced. But it is desirable, for the interests both of the medical profession and the public, that the line of demarcation between the data which medical witnesses may supply, and the conclusions which lawyers draw from them in reference to their own principles of practice, should be maintained. The province of medical advisers in the above point of view may be clearly defined. It is their duty to point out any mental unsoundness existent in

the presumed delinquent, and to afford such information as may enable those before whom he is tried to appreciate its influence in rendering punishment ineffectual, and therefore inapplicable, or to avoid this supposition, where, according to the principles of the law, it must be deemed erroneous. Thus, in the case of Macnaghten, they would have suggested grounds for determining, whether at the moment of his murderous act he was aware of its criminality, or on any other grounds was rendered by his state of insanity incapable of committing a crime. Thus dealt with, medical evidence would become a safeguard to the public, and not exclusively to the offender.

In making these remarks, I strongly disclaim any tendency to depreciate the evidence given on former occasions by medical witnesses in this class of cases. In their reference to our profession the insane are objects of tenderness, and of curative treatment. It cannot be a matter of surprise, that we should be averse to consign to punishment those whom we are habituated to regard in this kindly relation, and that if we are virtually retained as advocates for them, we should do our best to screen our unfortunate clients.

APPENDIX.

3. This is not always the case. In the *Examiner* for the 10th of June, 1838, the following paragraph occurs:

"It was but lately we saw announced the discharge from the Cork Lunatic Asylum of a captain of an East India-man, who had murdered his crew of eight seamen in cool blood. He had put them in irons one after another for alleged disobedience; and the men had submitted, relying on the justice of their cause, and on obtaining redress when they should get home. But, when in irons, he beat out their brains."

In this awful case, what Jeremy Bentham terms particular prevention, as applying to the delinquent, and contrasted with the preventive effect of example, was required, since he was afterwards let loose on society. I should be very glad to know what security of this first kind was obtained against his perpetrating a second series of murders?

4. Surely this point is not sufficiently

considered in the course of education. A young person who already possesses at the hand of nature a brilliancy and depth of imagination scarcely compatible with a just preponderance of steady reason, is chosen, because he already possesses this faculty in a high degree, as one in whom it ought to be encouraged and expanded. Accordingly, that place of education is chosen for him which is most likely to foster his aspirations. His own ambition and the sympathies of his friends are alike enlisted in his taking a line favourable to the development of what they call his genius. He is commanded to luxuriate in classical literature; he is carefully led through all the flowery paths in which he is by nature too well inclined to stray; he learns, like the unhappy Collins, "to love fairies, genii, giants, and monsters; he delights to rove through the meanders of enchantment, to gaze on the magnificence of golden palaces, to repose by the waterfalls of elysian gardens." All this may be favourable to success in the pursuit of an imaginative profession, but it is very unfavourable to mental health in his case. In these respects the Lectures of Sir Joshua Reynolds breathe in every page wholesome instruction, not confined, indeed, to his own art, but coextensive with the entire range of the faculty of the imagination.

5. The term "moral insanity," frequently used in discussions of this kind, is calculated to give considerable vagueness to our reasonings on this subject, from its relations to another form of unsoundness. Insanity is most conveniently viewed as a disease of the intellect; but, as such, it can scarcely fail to interfere with moral conduct and feelings. It will, indeed, be often observed, that long before the understanding has lost its control over the chain of our reasoning, it has ceased to restrain our conduct. In this way it is that so many unfortunate persons are ruined in their means long before they have been convicted of insanity. The disease is discovered too late. This state may very well be called "moral insanity," or rather "the moral phenomena of insanity." But far removed from this state, as involving, indeed, no lesion of the understanding, but being an original disease of the

emotive—the moral part of our nature, is the disease alluded to in the text as existing in Lord Ferrars. The moral symptoms which spring out of insanity, properly so called, may participate in any claims to impunity which the disease possesses. But “brutality” (the name which I have ventured to use for the contrasted disease), is strikingly distinguished from insanity in the circumstance, that whereas the sympathies of our nature, and the reason of the case, conspire to give some such immunity to the latter, they equally conspire to withhold it from the former; nay, they suggest that brutality, an original deficiency of the moral sense, can *only* be reached through penal infliction.

I have here given a brief sketch of a subject fully entered into in the work to which this essay constitutes a supplementary chapter; and previously in an essay on the Relation of the Theory of Morals to Insanity, which I published in 1834.

6. On the 2d of September, Thomas Rowe, a wine-cooper, aged 76, was discharged from the service of Mr. Thomas Waller, a wine-merchant in Cross Lane, on the ground that his faculties had given way, and that he did not know what he was about. On the 2d of October Mr. Waller received from him a letter, requesting Mr. Waller to give some other employment to the applicant, or to help him to one. On the 6th of October, Rowe calls upon Mr. Waller. Being admitted, he states that he has ineffectually sought for employment, and again urges Mr. Waller to take him into his service, either in town or in the country. Mr. Waller declines doing this, and expresses his opinion that Rowe must actually have saved enough to live upon. On another request for employment, reiterated by Rowe, and negatived by Mr. Waller, Rowe draws from his pocket a pistol, fires at him and wounds him, at a distance of two or three feet. He then draws another pistol, and observes to a person who prevents his using it, that such a person as Mr. Waller is not fit to live; an idea which he afterwards again expressed with equal force. Evidence was given on Rowe's trial, that latterly his faculties had much given way; that he frequently during the last

six months had appeared not to know what he was about, and complained of a giddiness of the head. The usual averments, that the defendant was unable to distinguish right from wrong, were made by the medical witness. It was argued, that the announcement which the prisoner had received from his master, that he could not employ him further, had upset his mind; that when the prisoner fired he was *incapable of reasoning*, from the great excitement under which he laboured, &c. Mr. Ballantine, for the prosecution, contended that “it must not go forth to the world that trivial acts of eccentricity or absurdity were to be held as an answer to crime; neither must it be understood that persons upon such grounds were to receive immunity when they had committed a grievous crime.”

Mr. Justice Maule having summed up, the jury almost immediately acquitted the prisoner, on the ground of insanity. This elderly person is therefore very comfortably provided for, the rest of his life, and a very convenient suggestion is afforded generally to servants out of place. All this is strangely wrong, even in relation to the existing state of our law. No evidence appears to have been adduced in proof of such mental unsoundness as is required to prevent the infliction of the legal punishment for an attempt to murder. Again, supposing this punishment is offensive to our sympathies, ought it to be exchanged for absolute impunity? Surely not.

The above trial and its results seem one of the first fruits of that of Macnaghten, with this difference, however, between the cases, that the crime of Macnaghten entails upon a man of property some privation of his means of enjoyment, while Rowe's transgression provides a pauper assassin with a comfortable livelihood. This case, indeed, and that of William Haynes, tried for the murder of his wife, by experiments made on her for the purpose of procuring abortion, and escaping absolutely unpunished, are grievous proofs of the inefficacy of our criminal law, or of the principles on which it is applied.

PNEUMONIA COMPLICATED WITH PLEURITIS.

To the Editor of the Medical Gazette.

SIR,

If the enclosed case is deemed worthy of insertion in your journal, its insertion will oblige

Your obedient servant,

JOHN CHRISTIE.

Keith, Banffshire, Nov. 30, 1843.

James Leslie, Cairnfield, Kenzie, aged 69, a small farmer, for two or three past winters liable to a dry, hacking cough, and slight difficulty in breathing.

After exposure to fatigue, cold, and wet, he was suddenly seized with severe pain in his right side, and, to a much greater extent than usual, with dyspnoea and cough.

A medical gentleman in his neighbourhood saw him at the commencement of his illness, but only prescribed some doses of medicine which acted severely on his bowels, which were at first costive.

On the 18th November, 1843, I was requested to visit him, and on doing so found him propped up in an arm chair, in which position, he said, he could only breathe with any degree of ease. At this time he had been about eight days ill, and the pain in the side was very much less than at the outset; but he was harassed by a cough which, to use his own words, he could not "get under," and the dyspnoea prevented him from resorting to the recumbent position at any time. He was so weak that he could hardly support the exertion of speaking, or rather whispering, in answer to my questions.

The tongue was loaded and white; urine scanty and high coloured; bowels for some days very loose, and stools slimy; pulse 60, small, and very compressible; sputa tenacious and reddish; respiration quick and shallow; skin cool and clammy; feet slightly oedematous; countenance of an anxious and despairing cast; and the lips and cheeks almost livid from congestion.

The motions of expansion and elevation of the ribs did not take place in any appreciable degree on the right side; and no vocal or tussive vibration could be distinguished in it.

The stroke sound of percussion was

completely dull over all the side; and the sense of resistance so much increased that it could only be compared to it as elicited by tapping the thigh. Pressure applied to the intercostal spaces, which were almost obliterated on both sides, occasioned severe pain.

No modification of bronchial respiration, or of the resonance of the voice, could be made out; in fact, no sound of any kind, normal or abnormal, was present on the right side.

On the left side percussion gave, throughout all its extent, a loud, prolonged, and high-pitched stroke sound.

The chest was on both sides flattened laterally, but rounded, and bulging anteriorly and posteriorly; and the motions of the ribs on the left side were very limited.

The respiratory murmur was weak, and its inspiratory sound imperfect and jerking, while the expiratory was prolonged; and the breathing seemed to be carried on more by the supplementary muscles than by those which, in a state of health, peculiarly promote the respiratory acts.

DIAGNOSIS.—*Pleuro-pneumonia, with complete hepatization of the right lung, and tense emphysema of the left.*

He gradually sank, and died on the evening of the 21st, three days subsequently to the period at which I first saw him, but no inspection of his body could be obtained.

REMARKS.—This case is interesting and instructive in regard to the diagnosis of pleuro-pneumonia in the aged, and illustrates the value of a knowledge of the progressive changes which the structure of the body undergoes at an advanced period of life. At that time, the resonance of the chest, even in health, is greater than at an earlier period; and it is especially the case where the muscular system is atrophied, fat absent, the cartilages of the ribs ossified, and the chest, although flattened in one direction, projects in another, and forms an immobile, tense, elastic arch; while the air vesicles of the lungs are dilated, and retain within them a large proportion of the air inspired for a longer period than in healthy respiration.

A variety of causes contribute to produce immobility, deformity, and increased resonance of the chest in the aged; but when to these, as in the case

before us, pleuritis and hepatization of one lung, and tense emphysema of the other, are superadded, the signs *usually* considered diagnostic of pleuro-pneumonia are lost, and simply because no respiratory movement can take place.

To this it might be objected that even although the chest was immovably fixed on one side, bronchophony and tussive vibration might be conducted from the opposite side by the air contained in the trachea and bronchial tubes of the inflamed lung.

The absence of these signs, however, may be explained by the prostration of the vital powers of the vocal organs in common with those of the rest of the body, which, together with the state of the chest and its contained viscera, would render them inadequate to the formation of articulate sounds, possessing force enough to excite vibratory movements which could propagate themselves to any distance; and in the same way, the weak shallow respiration, dilated air-cells, and the almost immobile chest, would present insurmountable obstacles to the forcible and rapid expulsion of such a volume of air from the left lung as would throw the opposite side of the chest into tussive vibration, even supposing the air stagnant in the bronchial tubes of the hepatized lung afforded a ready medium of conduction towards the solidified tissues.

Besides, when hepatization exists to such an extent as in this case, the air-cells and the smaller bronchi are blocked up by a soft inelastic lymph, which, in consequence of these properties, weakens rather than promotes the intensity of any vibratile movements which take place, and effectually prevents them from traversing so large a portion of solidified pulmonary structure as intervenes between the large bronchial tubes and the surface of the lung.

Even when disorganization of a more solid nature than the lymph effused in the second stage of pneumonia prevents the access of air into the bronchial tubes, the vocal fremitus is often obscured, or altogether prevented. Mr. Tapson relates a case illustrative of the point, in which "the large bronchus leading to the right lung was very much pressed upon, and the texture of the lung itself condensed by carcinomatous depositions, and in this there was a complete absence of the vocal fremitus." (MED. GAZ. Vol. i. 1842-3, p. 425).

It may, perhaps, be assumed that this was a case of pleuritis in which effusion had taken place to such an amount as to compress the lung so as to prevent respiration; and in the absence of an inspection of the body it cannot be positively asserted that it was not. But so far as signs go, the proof lies in favour of the diagnosis already formed. Dilatation and detrusion of the thorax on the affected side usually take place when the effusion is so very extensive, and bronchial or blowing murmurs may commonly be detected under the clavicle or close to the spine; and when to the absence of these we add the character of the sputa and the state of the lung, (for it must be assumed, from the history of the case, and the appearance of the thorax, that previous to the illness a tense emphysema existed in both lungs,) it becomes all but certain that the case was one of pneumonia complicated with pleuritis. The emphysematous condition of the left lung was inferred from the high pitch of the stroke sound; the obliteration of the intercostal spaces; the projection and immobility of the chest; the prolonged expiration and imperfect inspiration; the laborious breathing; the lividity of the cheeks and lips; and lastly, the habitual dyspnoea and cough.

The researches of M. Hourmann et Dechambre have established the fact that in the aged a natural emphysema exists, which may so far be considered normal. (Brit. and For. Med. Rev. Vol. i. p. 235.) And there can be no doubt that where there is a tendency, as in the old, to dilatation of the air-cells, slight causes will serve to give an impulse and direction to that which, to a certain extent, may be considered the natural structure of a particular period of life, and thus convert it into a state of disease which shall continue to progress until the pulmonary structure be completely disorganized.

CASE OF ABDOOL RAMON KHAN,

PRIVATE 1ST COMPANY GOLONDAUZE
BATTALION.

MR. LAWRENCE presents his compliments to the Editor of the MEDICAL GAZETTE, and forwards the narrative of a case, which he lately received from

India, with a request from the gentleman who treated it, Mr. Bowstead, surgeon in the Bombay army, that it might appear in one of the medical periodicals. The editor will be good enough to print it in the *GAZETTE*, if he should think it proper for publication.

Whitehall Place, Dec. 2, 1843.

I was called May 6th, 1843, soon after gun-fire, to the general parade ground, to see a native artilleryman who had been accidentally blown from a gun, while in the act of ramming home a blank cartridge.

The parade ground being adjacent to my house, no time was lost on my part in seeing my patient; I found him rolling on the ground, his mutilated arms writhing in agony: he was warm and sensible: I had him immediately removed to the hospital, and on carefully taking off his clothing I found he had sustained the following injuries:—Both of his hands and wrists were so dreadfully shattered that nothing remained but shreds of muscles, tendons, and dislocated and fractured bones. The ulnæ and radii of both arms were fractured in several places, and the flesh lacerated; the large bone of the right arm (or humerus) was fractured in pieces, and the parts forced into the shoulder joint; the left humerus had a compound fracture about midway between the joints with lacerations of the soft parts. His face and eyes were fearfully burnt, and he had sustained a severe blow on his chest; this was protected by the breast-plate, which was deeply indented by the force of the ramrod. On arriving at the hospital, finding that the nervous and circulating systems had not been overcome by the severe shock, and he still continued warm and sensible, I immediately amputated the right arm from the shoulder joint, in the usual manner. I also amputated the left arm about five or six inches below the shoulder joint; the poor fellow underwent these operations with the greatest coolness, never losing his senses, and it was only when both operations were completed (which they were in a very short time, the right arm was removed from the cavity in about a minute and a half,) he complained of faintness: a little hot brandy and water soon revived him, and he never had any signs of a collapse. It

is useless my entering into a very minute detail of the operation, further than stating, that I made my native assistant press a door-key covered with a piece of lint on the artery as it passes over the first rib. I then made a semi-circular incision below the joint, turning up the deltoid muscle and liberating the bone from its cavity; I then passed my knife under the bone, and formed my under flap by dividing the soft parts, arteries, &c. I immediately applied a ligature to the arterial main branch, which was the only vessel I had to take up. The left arm was taken off in the usual manner, and I had only to tie one artery: it was unfortunate the ligature silk was much too thick, but the case did not allow me to wait to remedy this. I visited him several times during the morning, and found him going on very nicely.

12 P.M.—Skin was rather hot, and a little oozing of blood from the stumps, but not more than would be expected; feels more pain; he is rather thirsty.

2 P.M.—Is a little restless, and begins to feel more pain; is more thirsty; his skin moist, not very hot.

R Soda Carbonas, ʒss.; Tinct. Hyoscyami, Vini Antimon. Tart. aa. ʒss.; Aq. Puræ, ʒiss. M. fiat haustus, to be taken with a proportion of acid citric effervescence, every two hours.

5 P.M.—Skin is not so warm; he is, as he has always been, quite sensible; breathing regular; the burn on his face pains him considerably; in other respects he says he is easier. The stumps appear all right: are getting a little hot. Apply cold water which evaporates freely during this month, from the hot winds.

Rept. Haustus saline, c. anodyne.

8 P.M.—His skin is naturally warm, and his pulse is not much excited: not so restless; he doses, and does not complain of much pain.

To take lemonade now and then. Rept. Haustus Salinae occasionally; omitting the Tinct. Hyoscyami.

R Calomel, gr. v.; Pulv. Jacobi. gr. ij.; Acet. Morphia, gr. ½. M. ft. Pilula. l. s. s.

May 7th.—At midnight sleeping, and going on right.

3 A.M.—The same as at 12 A.M.

5 A.M.—Skin is naturally warm, and pulse pretty regular.

Continue the cold lotion.

Bowels have not been moved.

Habt. Magnes. Sulph. ʒvi. ; Vini Antimon. Tart. ʒss. ; Tinct. Hyoseyami, ʒss. ; Aquæ. Menth. Pip. ʒij. statim.

5 P.M.—He appears to be going on very well ; he is cheerful ; bowels have been moved once ; motions rather dark.

When the stumps get hot continue the cold water. Rept. Pilulæ c. Calomel et Pulv. Jacobi. &c. h. s. Continue Haustus Salinæ pro re nata.

9 P.M.—Quite tranquil.

11 P.M.—Still going on well.

11th.—The stumps are doing well ; slept well, and does not complain of much pain, with the exception of his face and eyes ; bowels have not been moved.

Rept. Haustus aperiens c. Magnesic Sulph. &c.

1 P.M.—Has a little heat of skin, and lately been drowsy ; his heart, and the arteries of the body, pulsate much more than usual.

Continue Haustus Salinæ ; add Tinct. Digitalis, ℥x. pro re nata ; Habt. Calomel, gr. j. ; Antimon. Tart. gr. $\frac{1}{8}$; Acet. Morphia, gr. ss. omni nocte.

9th.—He has had a very easy and quiet night ; complains of but little pain, with the exception of his eyelids, on which are two ulcers : the extensive burn on his face doing very well. The stumps appear to be healing, particularly at the shoulder : they have been dressed. The pulsation has much abated.

5 P.M.—Going on very well ; no unfavourable symptoms.

Rept. Pilulæ h. s. Continue Haustus Salinæ.

10th, 6 A.M.—Has had a very good night ; stumps are healing, and look healthy : the ligatures not come away.

Habt. Decoct. Cinchona, ʒss. ; Tinct. Cinchona Co. ʒj. ; Acid. Nitr. dilut. ℥xv. bis in die.

Vesperæ.—Going on well. Cont. Pil.

11th.—On dressing the left arm, which was amputated below the shoulder-joint, a little coagulated venous blood come away from the ligature opening. After this, till May 25th, taking mild alteratives and tonics, with mild aperients, he gradually got quite well : the ligatures were a long time in coming away, owing, I think, to the thickness of the silk. As he suffered no pain from them I did not think it necessary to

use much force. The burn on his face got quite well, but the sight of his left eye, I fear, is lost ; not from inflammation ; indeed, the eye appears perfect.

REMARKS.—The singularity in this case is, that a man receiving such extensive and severe injuries, the nervous and circulating systems should not have been affected for such a length of time that I was allowed to convert an extensive injury, the nature of which I have detailed, into two simple incised wounds ; consequently no shock on the system came on, and he recovered without any unfavourable symptoms. The left arm did not heal as regularly as usual, but I think it was owing to the bruised state of the muscles, and the thickness of the ligature. I must beg to say the man is 21 years old, athletic, and possesses great mental and physical powers. I was unfortunate in not having other professional aid, as at that time I was the only surgeon within thirty miles. After the accident, the time occupied between it and the patient being put into his cot after the operations, was about forty minutes, five of which were taken up by getting a dooly (or vehicle) to remove him to the hospital ; the deciding, preparing for the operations, and performing them, took up the rest.

J. BOWSTEAD,

Surgeon, 2d Grenadier Regt. N. I.

Sattara, Sept. 28, 1843.

ON THE NERVES OF THE UTERUS.

By R. D. GRAINGER, Esq.

(For the London Medical Gazette.)

I HAVE derived great pleasure from examining the dissections of the uterine, vaginal, and vesical nerves, made by Dr. Lee.

The trunk and branches of the sympathetic nerve being left, as well as the trunks of some of the sacral nerves, afford a satisfactory clue in the examination. The injection of the blood-vessels affords a further and valuable aid in testing what are, and what are not, nervous fibrils.

After carefully inspecting and examining these beautiful dissections, I have no hesitation in expressing my conviction that they bear out fully and

entirely the delineations and descriptions published by Dr. Lee.

1. The preparations show an unequivocal continuity of fibres proceeding from undisputed nervous structures, the sympathetic and sacral nerves, to the newly discovered ganglia of the uterus, vagina, and ureter.

2. The nervous branches of the newly discovered ganglia join in various directions with acknowledged nerves, such as those of the inferior mesenteric plexus furnishing the hæmorrhoidal nerves, and with the spermatic nerves descending on the uterus from the folds of the broad ligaments.

3. The occurrence of small ganglia and gangliform enlargements, or the newly discovered nerves, are very characteristic, and corroborative of their real nature.

4. The nerves are accompanied by injected blood-vessels in a manner not seen in elastic tissue, though usual with the ganglionic nerves.

5. The ganglia discovered by Dr. Lee for the most part present in their form and disposition, and in the openings they possess, a perfect and entire correspondence with the larger ganglia of the sympathetic.

After the examination I have made, it certainly appears to me impossible for any one to arrive at a just conclusion respecting the true character of Dr. Lee's description without a careful inspection of his preparations.

It is proper to add, I have not yet had an opportunity of making a microscopical examination.

MEDICAL GAZETTE.

Friday, December 15, 1813.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

STATISTICS OF THE ROYAL COLLEGE OF PHYSICIANS.

THE Royal College of Physicians of London have just put forth their annual catalogue of Fellows and Licentiates. When we reflect that London

contains a population which, two years and a half ago, was ascertained to amount to 1,875,493 persons, and may now be fairly estimated at one million nine hundred thousand souls, it is not an idle inquiry, how is this prodigious multitude of human beings supplied with medical attendants? We will take some other opportunity of investigating the number of surgeons and general practitioners. Our present business is with the number of licensed physicians.

The actual number of Fellows on the new College list is 159; candidates for the Fellowship 4; Licentiates 269; Extra Licentiates 182. Total 614. The number of Licentiates promoted to the Fellowship during the last year, were 9; viz. Sir Robert Chermiside (elected some years back), Dr. Thomas Thomson (of Tunbridge Wells), Dr. Sayer, Dr. Webster, Dr. Dowler, Dr. Stollerforth, Dr. Rigby, Dr. Blakiston (of Birmingham), and Dr. Arthur Farre. Seven deaths took place among the Fellows, viz. Dr. Mytton, Dr. John Latham, Dr. Franck, Dr. Baneroff, Sir Charles Morgan, Dr. Cope, and Dr. Williams (of Ipswich). The order of Fellows therefore has gained an accession of two members only. Of the 159 Fellows now on the College list, 72 have either retired from practice, or are resident in the country. The number of practising Fellows, therefore, resident in the metropolis, is 87.

Nine Licentiates have been added to the list during the past year. Nine (as we have just seen) have been promoted, and seven have died; viz. Dr. Wightman, Dr. McDougle, Dr. Thomas Burder, Dr. Ridgway, Dr. Charles Phillips, and the two Drs. Lilburn, who died, we believe, within three months of each other, the one in Candia, whither he had gone as Consul, and the other in London. The Licentiate list therefore is diminished by 7.

It was last year 276. It is now, as we have stated, 269. Of these 269 Licentiates, borne on the College list, no less than 146 have either retired from practice, or are resident beyond the metropolitan district. This reduces the number of practising Licentiates to 123, which, added to the 87 practising Fellows, gives a grand total of 210 physicians nominally available for the public service in the metropolis. But we may fairly presume that twenty of that number are from various circumstances (ill health, frequent absence from town, &c.) hardly to be looked upon as candidates for employment. This brings the number of physicians actually practising in London and its immediate environs, to 190, which is one for every ten thousand of the population. No one, we think, can say, after this, that London is overstocked with physicians. There is scarcely a town in England numbering a population of ten thousand, which does not contain two; and many contain three, or even four, physicians. We are inclined to believe, however, that such an amount of population does not adequately support more than one physician. The maximum appears to have been reached in London. By referring to the table with which this notice concludes, it will be seen that the actual number of metropolitan physicians is less this year than last by five.

We come now to the class of Extra Licentiates. No less than 41 new members have been added to this class, and as only one death in their number is recorded (Dr. Stock, of Bristol), this division of the College list is augmented by 40. The numbers last year were 142. This year they are 182. The Extra Licentiates, it will be remembered, are country practitioners, examined and licensed by a board differently constituted from that which examines and licenses those destined

for practice in the metropolis, and *seven miles round it*. This phrase, by the way, now that the metropolis extends from west to east (from Hammer-smith Bridge to Woolwich) very nearly ten miles, is become a somewhat obsolete mode of expression, indicating, in a manner not to be mistaken, the necessity of that reform in College affairs which we presume cannot be much longer delayed.

We do not clearly understand the cause of this sudden fondness which has risen in favour of the Extra Urban license of the College of Physicians. It seems to denote a wish to nestle under the College wings, but we suspect there is something at the bottom of this new-born zeal more than we have been able to fathom. It is hardly worth while to inquire, for the class of Extra Licentiates is doomed to a speedy decay. The forthcoming charter of the College signs the death-warrant, not of our good friends the 182 provincial physicians, but of the order to which they belong.

It may be interesting to some of our readers to compare the present numbers, as borne on the College books, with those which the same books presented in an earlier age. For instance, in 1820, the College of Physicians numbered 99 Fellows (including sundry Candidates for the Fellowship,) 200 Licentiates, and 39 Extra Licentiates. Total 338. Thirty-four years ago, viz. in 1809, when Dr. Hue was the youngest Fellow, the College bore upon their books the following numbers: 59 Fellows; 4 Candidates for the Fellowship; 152 Licentiates; 5 Licentiates in Midwifery; and 35 Extra Urban Licentiates. Total 255.

If we carry on our retrospect still farther back, we shall find something to amuse if not to instruct us. The gradual falling off in the number of Doctors, in a proportion equalling, as we may well

believe, the lesser amount of the population, is well worthy of note.

In 1788, the College numbered 42 Fellows, 87 Licentiates, 8 Licentiatees in Midwifery, and 29 Extra Licentiatees. Total, 166.

In 1765, the Fellows had increased in number from 42 to 63, but the Licentiatees had fallen off so greatly, that the total number of practising physicians was only 110.

In 1746, a new feature meets us. The number of Fellows in that year was 56; but in this list are comprised two dukes, viz. the Dukes of Richmond and Montagu. In those palmy days—never, we fear, to return—the nobility were as much flattered by possessing the degree of Doctor in Medicine, as their successors are now, at an installation, by having conferred on them the corresponding honour in civil law. Besides the 56 Fellows, there were then 2 Candidates, and 24 Licentiatees, forming a total of only 80. It is worthy of note that while in the year of which we are treating (1746) there were 54 practising Fellows, in 1788, forty-two years afterwards, there were but 42 Fellows. The College had, for some reason or other unknown to us, become chary in the distribution of the fellowship, or else the profits of doctors had materially declined.

We will now go back to the 17th century. In 1695, during the reign of King William III. the profession of physic flourished far more than it did fifty years afterwards, in the reign of George II.; at least, if we may judge from the numbers who came forward to share in its honours and emoluments. In that year, when Richard Morton was at the head of his profession in London, the College list contained no less than 130 names; viz. 70 Fellows, 11 Honorary Fellows, 8 Candidates, and 41 Licentiatees. In 1677 (reign of Charles II.), when Sydenham had

reached the zenith of his fame, the number of licensed metropolitan physicians had sunk to 80; namely, 53 Fellows, 12 Candidates, and 15 Honorary Fellows. No Licentiatees appear in this year's catalogue.

In 1650, the total number on the College-list was 47, of course all Fellows. In 1618, during the reign of James I., the total number of physicians practising in London with the College diploma was 34. In this year, the College of Physicians published the first edition of their *Pharmacopœia*. And here we shall pause in our retrospect of the statistics of the Royal College of Physicians. We have seen their number steadily retrograding from 1843 to 1618; or, to reverse the order of procedure, we have seen them progressively advancing, in the course of two centuries and a quarter, from 34 to 614. It has been calculated that in 1618 the population of London was under 350,000. The 34 physicians of that period, therefore, afforded one physician to every ten thousand inhabitants; and this we have already shewn to be the exact proportion subsisting at the present time between the givers and takers of physic in this metropolis. A curious coincidence certainly, but calculated, also, to teach us, that in all ages of the world there has been the same proportion of urgent and acute cases, the same proportion of patients in the richer and poorer classes of society, and the same necessity felt for grades of professional rank.

We shall conclude these brief notices of collegiate statistics by informing our readers that the oldest living physician on the College-list is Dr. Edward Roberts, who became a Fellow in 1792; and that the oldest practising physician in the metropolis is Sir Henry Hallford, the President, who entered the portals of the College exactly fifty years ago, (1793). *Diu nobis intersit.*

Statistics of the Royal College of Physicians of London from 1618 to 1843 (225 years).

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

November 28, 1843.

MR. STANLEY, President, in the Chair.

On the Cause of the occasional presence of Spermatozoa in the fluid drawn from the sac of common hydrocele of the tunica vaginalis. By JOHN DALRYMPLE, Esq. Surgeon to the London Ophthalmic Hospital.

THE author commenced by referring briefly to the cases published in the last volume of the Society's Transactions, where spermatozoa were found in the fluid drawn both from encysted and from common hydrocele. According to his own observations, these bodies are generally much less numerous in the latter than in the former kind of the disease, and the explanation which he offered of the mode in which they become mingled with the fluid of common hydrocele, when evacuated by the trocar, was the following. He quoted the authority of Scarpa to shew that when the tunica vaginalis becomes distended with fluid, the different vessels of the spermatic cord are separated from each other to a greater or less distance, owing to the gradual expansion of the membranes, and the epididymis and vas deferens are consequently removed out of their natural places in reference to the body of the testicle. He likewise presented to the Society a preparation, with a drawing, of a hydrocele, in which that condition of the tubes of the testis was exhibited. The testicle was situated at the posterior and inferior part of the sac, and somewhat internally: the vascular cord was seen running along the posterior wall, the vas deferens being about one inch distant from it, and to the outside; at the lower part of the sac, the vas deferens approached the testis, made a few large coils, from which commenced the

lower head of the epididymis; as this body ascended again, it was seen to be separated to the distance of an inch and a half from the testis, and to lie on the lateral aspect of the sac. Above the testis, the position of parts was as follows:—The vascular cord at the most posterior part of the sac; the vas deferens next to it, but distant about half an inch; and, lastly, the epididymis, still more external, and anterior to the vas deferens. At the upper part, the epididymis suddenly crossed the vas deferens, and descended in a curved line towards the body of the testicle, in which it finally merged.

The author concluded by expressing his opinion, that in cases of common hydrocele, the epididymis and vas deferens are placed by no means out of danger of being punctured by the trocar, in the operation of tapping; and added, that the wounding of even a single tube might well afford the few spermatozoa found in the specimen of fluid referred to above, the more especially when we remember the squeezing often made to evacuate the last few drachms of the contained fluid.

Cases of Carcinoma of the Thyroid Gland.

By CÆSAR HAWKINS, Esq., Surgeon to St. George's Hospital.

THE author began by adverting to the common opinion that malignant tumor rarely commences in the thyroid gland, and stated his belief that this body is more frequently the seat of primary scirrhus than is usually supposed. In confirmation of this view, he related, in the first place, a case which was under his care in 1837, where the tumor appeared to be of that nature, but in which he had not the opportunity of making a *post-mortem* examination to verify his diagnosis; and he then alluded to four other cases which had come under his observation. He re-

marked that the age of the patient, when the disease commenced, was from 45 to 65; at which period of life ordinary bronchocele very seldom takes place, and the tumors most likely to present themselves are the serous tumors, developed in or near the thyroid gland, or the cartilaginous or osseous degenerations, lately described by the term *enchondroma*. Having pointed out the diagnostic marks by which these tumors may be distinguished, and dwelt on the chief characters of carcinoma affecting the gland, he proceeded to relate the particulars of a case recently under his care in St. George's Hospital; his description being illustrated by coloured drawings, made during the life of the patient, and from the morbid parts found in dissection, and by preparations.

Without following the author through the details of the case, it may be mentioned that the tumor which extended on both sides from the thyroid gland, was found to have attained a large size, and the parts adjacent to the larynx and œsophagus were involved in its texture, which presented the usual appearance of true scirrhus. A large ulcer opened on the surface of the œsophagus where the tumor adhered to that tube; and another ulcerated opening led into the trachea, immediately below the cricoid cartilage. The right internal jugular vein was closely adherent to the tumor, its coats having been absorbed at one part, and a small portion of the morbid structure having projected into its interior. The pneumogastric nerve was much flattened, and its fibrils were separated, so as to present a plexiform appearance; the carotid artery was deeply imbedded in the tumor. In describing the thyroid gland, the author observed that this body had nearly disappeared, the only part remaining being a small portion of the left lobe, intimately joined to the tumor, so as to shew that they were originally parts of the same body; and there was a complete line of demarcation between the two structures.

Cysticercus Cellulosa of the Brain. By
DREWRY OTTLEY, Esq.; communicated
by JOHN FORBES, M.D., F.R.S.

THE author remarks, that the presence of *cysticerci* in the brain is sufficiently rare to warrant, he thinks, the communication of a single case, which moreover possesses an interest as being the only one, as far as he can discover, in which an opportunity was afforded of watching the progress of the disease from an early period, and also from there not being any complication likely to disturb the cerebral functions; so that the symptoms observed were evidently due to the presence of the parasitic animals.

The patient was a woman, forty years of age,—for many years a sufferer from emphy-

sema of the lungs and bronchitis. In the early part of 1838 she began to complain of frequent giddiness, and a dull stupifying pain in the head. In July of that year she suffered from temporary numbness and loss of power in the right hand and arm, with some confusion of intellect and difficulty of articulation. Cupping relieved her; but the symptoms returned again, and after a time the giddiness became more constant, and the loss of memory and confusion of intellect more considerable. In 1830, she became subject to fits, during which there was entire loss of consciousness, and convulsions. They differed from epileptic fits in being less sudden, both in their invasion and termination. The recovery from them was also slower, for she often remained for two or three days in a stupified state. During the last twelve months of her life the pain in the head was constant, though never extremely acute, her sight became dim, and the convulsions recurred more frequently. At the end of October, 1840, after frightful convulsions for twenty-four hours, she expired.

The state of the brain after death is thus described:—The vessels on the surface of the brain were somewhat congested, and the sub-arachnoid cellular tissue infiltrated with serum. Numerous small fibrous cysts were found in the pia mater covering the surface of the hemispheres, and dipping between the convolutions of the brain. The cysts were present on both sides, but were most numerous on the surface of the left hemisphere. They varied in size from that of a pea to less than a peppercorn; they were seated in the pia mater, but had become partially imbedded in the grey matter of the convolutions. None existed in the white matter, in the central ganglia, nor in the plexus choroides. A few were found at the under surface of the cerebral convolutions, but none either in the cerebellum or medulla oblongata. The cerebral tissue around these cysts appeared natural as to colour and consistence, and the brain generally, except for the presence of these animals, would have been termed healthy. There was rather more fluid than natural in the ventricles, and at the base of the brain.

Several of the cysts were afterwards examined, and each was found to contain a vesicular worm, consisting of a posterior transparent vesicle, in which the anterior cylindrical portion or body, furnished at its extremity with four suckers and a double circle of hooks, lay retracted, like the finger of a glove turned in, and could be expelled by gentle pressure on the containing vesicle; in short, answering exactly to the description given of the *cysticercus cellulosa* of Rudolphi.

Abstract of a Paper on the State in which Uric Acid exists in the Urine. By H. BENEE JONES, M.A. and M.D. Communicated by Caesar Hawkins, Esq.

BERZELIUS mentions Dr. Prout's view of the uric acid existing as urate of ammonia, and then states his own, that uric acid most frequently is in an uncombined state, though modified by the presence of other matters. Dr. Prout adheres, in his last edition, to his own opinion. Dr. Simon thinks that urine may contain free uric acid, and also urate of ammonia, &c. Becquerel considers uric acid exists, combined with colouring matter and extractive matters. I first examined the appearance and properties of the reddish deposit obtained from urine by evaporation, under the air-pump. When examined with the microscope, this is always in the form of minute globular particles, too small to be measured. Some of the deposit was washed with alcohol, dried and dissolved in boiling water; after standing ten hours, no deposit took place, so that the point of saturation might not have been reached. A weighed quantity of fluid, at temperature of 64 deg. Fah., evaporated to dryness, showed that one part of residue was dissolved in, at the most, 1349 parts of water. Some urine, which, on standing twelve hours, gave a deposit, was filtered; a weighed quantity of the urine, at 64 deg. Fah., showed that one part of uric acid remained in at most 2567 parts of urine.

Healthy urine, specific gravity 1027, evaporated *in vacuo*, until it gave a deposit, was filtered; a weighed quantity of the clear fluid showed that one part of uric acid remained in at most 2789 parts of urine.

M. Becquerel states the usual quantity of uric acid is, one part of uric acid to between 2000 and 3333 water.

M. Lecanu states the quantity of uric acid is one part of uric acid to 780—1030 water.

By three analyses of the needles I obtained in 100 parts of substance—

	1st.	2d.	3d.	Theory.
Uric acid	87.65	87.09	86.40	86.58
	(One equivalent of uric acid.)			
Ammonia . .	9.32	9.29	9.12	8.77
	(One equivalent of ammonia.)			
Loss . . .	3.03	3.62	4.48	4.63
	(One equivalent of water.)			

I tried in every way to obtain another urate of ammonia, but did not succeed. I then tried if the needle could be modified, so as to have the appearance of the ordinary urinary sediment.

When the needles were boiled with healthy acid urine, they were dissolved, and after a time a deposit took place, precisely similar to the ordinary deposit. When cold, the clear urine was again poured off,

I then examined the appearance and properties of pure urate of ammonia, obtained by boiling strong ammonia with uric acid. Under the microscope this substance is seen to consist of small needles, which form tufts and crosses.

In slightly ammoniacal solution, one part of urate of ammonia required 1118 of ammoniacal water to hold it dissolved. When perfectly dried over sulphuric acid *in vacuo*, the needles were re-dissolved, and the solution reddened blue litmus paper.

In water, which was perfectly pure, some needles were dissolved.

After standing twelve hours, to give a deposit of excess of urate of ammonia, the solution was filtered; a quantity weighed at the temperature of 69 deg. Fah., showed that one part of nitrate of ammonia remained in 897 parts of water.

A second experiment gave, at the temperature of 67 deg. Fah., one part of urate of ammonia to 1012 water. A third experiment, with needles prepared at another time, gave one part of urate of ammonia to 996 water, at 69 deg. Fah. A fourth experiment, in which evaporation took place under the air-pump *in vacuo*, one part of urate of ammonia required 1018 parts of water, at 59 deg. Fah.

By exposure for a considerable time to heat, even below 212 deg., the needles of urate of ammonia are decomposed; crystals of uric acid may be detected with the microscope. If to a solution of these needles, which is just so strong that it gives no precipitate on standing twenty-four hours, the smallest quantity of very dilute liquor ammonia, or small quantities of muriate sulphate, or acetate of ammonia, are added, a deposit falls in a few minutes. The precipitate is, with the two last, changed in form; no needles are seen, only globules. On the addition of any acid, the needles undergo a change.

and boiled with fresh needles; the ordinary deposit again took place, as it did also a third time.

To a hot solution of needles in water, so little urine was added, that the deposit on cooling was quite uncoloured; with the microscope it consisted of globules.

Some of the needles were dissolved in hot water, and some pure urea was added; still the deposit on cooling consisted of needles.

Excess of uric acid was used, and still needles were deposited.

I next tried common salt; with this the deposit was precisely similar to the deposit in urine. In making this experiment I observed that the deposit was far less than with pure water, and I found that one part of urate of ammonia with rather more than one part of salt, requires only 466 parts of water at 71 deg. F. One part of urate of ammonia

with nearly two parts of salt, required 468 parts of water, at 67 deg. F., and one part of urate of ammonia with two-thirds of one part of salt, requires 703 parts of water, at 68 deg. F.

These, and the previous results, may be compared in the following table; the experiments having all been made on hot saturated solutions, which stood until they deposited crystals.

In ammoniacal mother liq.	at 65 deg. F.	1 urate of amm.	to 1118 water.
In pure distilled water	at 67 deg. F.	ditto	ditto . 1012 ditto.
Ditto ditto	at 59 deg. F.	ditto	ditto . 1018 ditto.
Ditto ditto	at 69 deg. F.	ditto	ditto . 897 ditto.
Ditto ditto	at 69 deg. F.	ditto	ditto . 996 ditto.
Little salt and distilled water	at 68 deg. F.	ditto	ditto . 703 ditto.
More salt	at 71 deg. F.	ditto	ditto . 465 ditto.
Most salt	at 67 deg. F.	ditto	ditto . 468 ditto.

If a great excess of salt was used, the urate of ammonia became as insoluble as in pure water.

From these experiments it appears that urate of ammonia, when dissolved with about an equal quantity of salt, acquires a peculiar degree of solubility in water, and a different appearance from pure urate of ammonia.

The appearance is identical with that deposit obtained from urine, and the solubility beyond the largest quantity which Lecanu observed in the urine.

I next tried what effect the salt would have on pure uric acid. I found one part of uric acid remained dissolved in 8,941 parts of water, at 68 deg. F., and one part of uric acid with salt remained in 7,199 parts of water at 64 deg. F. These results tend to establish Dr. Prout's opinion, shewing

how urate of ammonia is modified in form and in solubility.

The experiments may give a further insight into the various causes of that frequent deposit of urate of ammonia which occurs in healthy urine.

Salt may increase or diminish the solubility of the urate of ammonia, according as it is in moderate quantity, or in great excess. The sulphate, the muriate, and the acetate of ammonia, lessen the dissolving power of water. Each salt that occurs in the urine has most probably some effect on the solubility of the urate of ammonia, and it may be, by a very extended inquiry into the relative re-actions of the different salts, that we may arrive at an accurate knowledge of the causes of the occasional deposits in healthy urine.

UNIVERSITY OF LONDON.

EXAMINATION FOR THE DEGREE OF DOCTOR OF MEDICINE.—PASS EXAMINATION.

Monday, Nov. 27th. Morning, 10 to 1.

Logic and Moral Philosophy.

Examiners, Mr. Burcham and the Rev. H. Alford.

1. Give an account of the sensualist and idealist philosophies.

2. Criticise generally the Essay concerning Human Understanding; its method, objects, arrangement, and style.

3. In what sense does Locke use the word "Understanding?" What other senses have been given to it?

4. What are Cousin's remarks on Locke's procedure in examining the origin of our ideas? State your own opinion on the proper order of our inquiries concerning Human Understanding.

5. Translate the following passage, and

accompany it with a brief statement of Cousin's arguments, of which it is a summary.

Locke a éprouvé son système sur un certain nombre d'idées particulières, savoir: l'idée de l'espace, l'idée de l'infini, l'idée du temps, l'idée de l'identité personnelle, l'idée de la substance, l'idée de la cause, l'idée du bien et du mal, s'imposant la loi d'expliquer toutes idées par la sensation et par la réflexion. Nous avons suivi Locke sur tous ces points qu'il a lui-même choisis; et, sur tous ces points, un examen attentif nous a démontré qu'on ne peut expliquer aucune de ces idées par la sensation ou par la réflexion, qu'à la condition de reconnaître entièrement les caractères réels dont ces idées sont aujourd'hui marquées dans l'entendement de tous les hommes.

6. Give the substance of Cousin's remarks on nominalism and realism; and examine critically the assertion of Locke and his school, that the greater part of our disputes are disputes about words.

7. In what instances have the followers of

Locke perpetuated or advanced his errors? In what have they corrected them?

8. Give a brief account of the purpose and proposed contents of the "Novum Organum." What place are you disposed to assign to Bacon in the history of philosophy?

9. "As the sciences now in being are useless in the discovery of works, so is the present logic in the discovery of the sciences."—*Aphor.* 11.

Of what sciences and what logic is this said, and with what justice?

10. Enumerate the classes of prejudices or idols described by Bacon, and give instances of them.

11. How do you answer the argument against a future state which is founded on the presumption that death is the destruction of living beings?

12. Show that a kind of moral government is implied in God's natural government. In what sense may the notion of a moral scheme of government be said to be natural?

13. Distinguish between instinctive and deliberate resentment. What is the final cause of the former?

14. What idea, according to Hume, have we of cause and effect? What are the objections made by him to the *a posteriori* argument for the existence of a Deity?

Commentary on a Case in Medicine.

Examiners, Dr. BILLING and Dr. TWEEDIE.

CASE.—A married woman, 25 years of age, came under observation on the 8th of June, and gave the following account of her illness. About six months previously she felt pain in the cardiac region, and vertigo, followed by loss of power in the left side of the body and loss of speech. On the following day she became insensible, and remained so for about a week, but after the adoption of energetic treatment, recovered her consciousness and the power of the left side of the face, but the command over the left upper and lower extremity was much impaired. She was in this state when she applied for advice on the 8th of June, and continued without perceptible change for four weeks, when the pain in the cardiac region increased, accompanied with strong impulse of the heart, and a rough rolling murmur with the first sound. The measures pursued had the effect of diminishing the impulse of the heart so much that she unadvisedly exposed herself to cold. When visited a few days afterwards she exhibited the following symptoms:—the breathing was laborious, the lips livid; there was however so much consciousness that she recognised persons around her, but her articulation

was indistinct and her voice feeble; the pulse became scarcely perceptible, the extremities cold, and she died in the evening.

What was the nature of her disease? What treatment would you have suggested? What appearances would you have expected to find on examination of the body after death?

A translation from Celsus, lib. iii. cap. ii.

Tuesday, November 28.—Morning, 10 to 1.

Medicine.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Describe the forms of hypertrophy of the heart. Give the symptoms, local and general, of each. What are the pathological effects of hypertrophy of the left ventricle?

2. Sketch the diagnostic symptoms and treatment of inflammation of the duodenum.

3. Detail the symptoms, varieties, and treatment of iritis.

4. Describe the diagnostic characters and forms of purpura, with the appropriate treatment of each.

Afternoon, 3 to 6.

1. When there is complete absence of the respiratory murmur over the whole of one side of the thorax, what inferences are to be drawn as to its pathological causes?

2. Detail the symptoms of scarlet fever, including a description of its several forms, and the treatment applicable to each.

3. Mention the sources from which the blood may issue in hemoptysis.

4. Enumerate the varieties of colic. Explain the causes, pathology, and appropriate treatment of each.

Tuesday, December 5.—Morning, 10 to 1.

Surgery.

Examiners, Mr. BACOT and Sir Stephen HAMMICK.

How do you know when a caries of the cervical, dorsal, or lumbar vertebrae is threatened? Give the symptoms and treatment of the different stages respectively by which the disease generally proceeds, when it goes on to its utmost limit, short of death, whether it has arisen from accident or a constitutional cause: give the symptoms, appearances, and management of the various curvatures of the spine, up to a favourable or fatal issue: detail the symptoms, by which you detect the existence of a psoas and a lumbar abscess: point out the diseases with which they are occasionally confounded, from their earliest to their more advanced stages; giving the various modes of treatment which have been from time to time recommended; saying which you would prefer, with your reasons for such preference; and where the case terminates fatally, either

from caries, curvature, or abscess, you will write down the state in which you expect to find the bony and soft parts, by a post-mortem examination.

Afternoon, 3 to 6.

If called to a person about the middle age, and apparently hitherto in good health, who has been found lying in the street in a state of total insensibility, how would you detect, whether that unconsciousness has arisen, from a concussion of the brain; an extravasation of blood within the head, from violence or natural causes; a fracture of the skull; apoplexy; epilepsy; drunkenness; or poison? Detail the symptoms of each of the above states respectively, and where you think the application of the trephine is necessary, you will give the method of performing that operation; contrasting the practice of the present day, in the treatment of capillary, simple and compound fractures of the skull, with that pursued by Mr. Pott and the best surgeons of his time, with your opinion of the superiority of one over the other.

Wednesday, Dec. 6.—Morning, 10 to 1.

Medicine.

Examiners, Dr. Billing and Dr. Tweedie.

1. Sketch the characteristic symptoms of asthma, including a description of its forms and complications. Mention the opinions entertained of its pathology or nature; and give an outline of the treatment applicable to each variety of the disease.

2. Explain the principles on which the treatment of dropsy should be conducted.

Afternoon, 3 to 6.

1. Describe the various forms of palsy, connecting each with its pathological cause; sketch the indications to be kept in view in the treatment.

2. Give an outline of the treatment of continued fever, including, 1. The circumstances that require the employment of blood-letting, general or local. 2. Those which render it inexpedient. 3. The indications for the exhibition of wine and other stimulants, with the rules to be observed in their administration.

Thursday, Dec. 7.—Morning, 10 to 1.

Midwifery.

Examiner, Dr. Rigby.

1. Describe exactly the manner in which the head presents and passes through the pelvis and external parts during labour, in the most usual form of cranial presentation.

2. Describe the different modes of treatment which have been adopted in ovarian dropsy, and their degree of success.

Afternoon, 3 to 6.

1. Describe the different varieties of deformed pelvis, and the causes of them.

2. Enumerate the various ways by which the child can render labour difficult or dangerous by its own faulty conformation.

CASE OF PRESENTATION OF THE ANTERIOR FONTANELLE.

By JOHN A. ELKINTON, M.D.

AUGUST 4, 1843, at 10 o'clock P.M., I was called to visit Mrs. F—, in labour with her second child. The membranes ruptured (in my absence from the room) a little before 11 o'clock the same evening. Labour progressed gradually, with the head presenting, and, as I supposed, with the occiput to the

left acetabulum. After waiting some hours, labour advancing slowly, pains continuing all the time feebly, os uteri fully dilated, and pelvis ample, I determined to give ergot, having previously used some tansy or pennyroyal tea, which was convenient, without producing any effect. The powdered ergot was first administered, and then the wine of ergot, neither of which produced any apparent uterine contractions. As the head was moveable, and would occasionally be pressed down by voluntary efforts, in conjunction with pains, so as to appear almost on the point of delivery, I determined to apply the forceps and deliver. The patient becoming exhausted, I commenced the application of the forceps about 4 o'clock on the morning of the fifth. The male blade was readily introduced, but I very soon found it impossible to adjust the female blade.

Without further delay I sent for Professor Hodge, who was soon present.

He attributed the delay and difficulty to a malpresentation of the head, the child presenting the anterior fontanelle instead of the posterior fontanelle, to the centre of the pelvis. The position was such, that the occiput was somewhat to the left side of the promontory of the sacrum; and the termination of the sagittal suture at the root of the nose, somewhat to the right of the symphysis pubis. Hence two difficulties existed. First, the occipito-frontal, or longitudinal diameter of the cranium, corresponded to the sacro-pubic, or short diameter of the superior straight; and, secondly, the forehead was anterior, the occiput posterior.

For a favourable delivery, two indications were to be fulfilled. First, to cause flexion of the head, by which the vertex (or posterior fontanelle) should descend first, and the occipito-bregmatic (or perpendicular) diameter of the head be substituted for occipito-frontal diameter; and second, to cause rotation, so that the occiput might eventually come under the arch of the pubis, and not to the coccyx and perineum. This was accomplished by Dr. Hodge, with the fingers alone; he made pressure behind the symphysis, on the rig't side of the os frontis, pushing it upwards so as to cause flexion of the head, and at the same time to the right and backwards, so as to direct the face towards the hollow of the sacrum, and of course the occiput from the sacrum to the left acetabulum and symphysis pubis.

Having thus effected this important change in the position of the child, I was requested to take charge of the patient, and in a few minutes she was delivered of a large and healthy child, without further interference or artificial aid.

The object in this brief notice is to record the peculiarity of the presentation, and to

confess the difficulty I have occasionally experienced in diagnosis. Who can positively determine the exact presentation of the child's head, in the early stage of labour? This case proves the importance of accurate distinctions in all varieties of presentation.

Philadelphia, Aug. 21, 1843.

CASE OF HEMIPLEGIA, CONSEQUENT ON TYING THE COMMON CAROTID.

By O. FAIRFAX, M.D.

OBSERVING in a late number of the Medical Examiner, an instance of hemiplegia, consequent on tying the common carotid, and believing it to be an unusual effect of the operation, and an additional and striking exemplification of the fact, that opposite conditions of the brain, as regards its supply of blood, may result in the production of some symptoms in common, I am induced to send you the following similar case.

On the 18th of July, 1842, in presence of Drs. Murphy, Powell, and Richards, of this place, I applied a ligature to the left common carotid, an inch above the clavicle, and my patient became hemiplegic as regards the limbs of the right side, but the face was not affected. The hemiplegia may have occurred at the moment of tying the ligature, but was not remarked by the attendants until an hour or more after the operation. The patient, who was a middle-aged lady, already much reduced by chronic disease of the lungs, remained faint and hemiplegic to her death, which occurred after five days, apparently from exhaustion. Her mental faculties continued perfect to the last hour.

Alexandria (D. C.), August 31, 1843.

QUEEN ELIZABETH SUFFERING FROM THE TOOTHACHE.

THERE were found at Islington, concealed in the house of a catholic priest, three waxen images of the queen, and two of her chief councillors, which it was said were intended to be operated upon in a diabolical manner for her destruction. Much at the same time Her Majesty was attacked with such grievous toothache, that nothing could mitigate the torture she endured, and she obtained no rest either by night or day. Some persons attributed these sufferings to the malign magic that had been employed against her. Her physicians held a consultation on the royal malady; and instead of devising a remedy for her relief, fell to disputing among themselves on the cause of her indisposition, and the medicines most advisable to use.

The lords of the council then took the matter in hand, and decided on sending for an "outlandish physician, of the name of John Antony Fenatus," who was celebrated for curing this agonizing pain; but as it was a perilous thing to entrust the sacred person of a sovereign, so suspicious of plots against her life by poison as Elizabeth, to the discretion of a foreign practitioner, "who might possibly be a jew, or even a papist," they would not permit him to see Her Majesty, but required him to write his prescription.

Fenatus composed a long and elaborate Latin letter in reply, declaring in the first place his unworthiness to come after such great physicians, and then prescribing divers remedies, but with the intimation that, if the tooth were hollow, when all was said and done, it was best to have it drawn, though at the cost of some short pain. If, however, Her Majesty could not bring herself to submit to the use of chirurgical instruments (of which, it seems, he had heard something of her abhorrence), then he advised that the juice of *chelidonium major* might be put into the tooth, and so stopped with wax that none of it might touch the sound parts; which would so loosen the tooth, that in a short time it might be pulled out with the fingers; or the root of the said plant might be rubbed upon the tooth, which would produce the same effect; but concluded by declaring that drawing the tooth was, by all, esteemed the safest and best way.

The courage of the lion-hearted Elizabeth failed her on this occasion; and she expressed so much repugnance to the loss of her tooth, combined with terror of the pain that might attend the operation, that the eloquence of her whole cabinet could not prevail upon her to undergo it.

Aylmer, Bishop of London, who was present at this grave debate, then stood forth; and after assuring Her Majesty that the pain was less than she apprehended, told her, "that although he was an old man, and had not many teeth to spare, she should see a practical experiment of it on himself," and thereupon, bade the surgeon, who was in attendance, extract one of his teeth in Her Majesty's presence, which encouraged the queen to submit to the like operation.—*Miss Strickland's Lives of the Queens of England.*

ON PUNCTURES OF THE EYE.

BY M. GUEPIN.

M. D. AN architect, brought his son to M. Guépin, in 1843. A minute fragment of iron had entered his eye, reaching from the cornea to the capsule of the crystalline lens, and almost touching the iris. It was impossible to grasp the fragment, and an incision would have been difficult, as it lay upon the upper edge of the pupil. M. Guépin

accordingly devised the following remedy. He prescribed a collyrium made with distilled water and acetic acid, being persuaded that if the fragment became oxidized at its corneal extremity, the oxidation would spread over its whole surface, and that the dissolution and absorption of the fragment would follow. The event justified his supposition. At the end of three weeks, the cure was complete, with the exception of an almost imperceptible white point upon the capsule, and a very slight cicatrix on the cornea. In another case, the same collyrium was again used with success to carry off the oxide of iron left in the substance of the cornea by a fragment of iron which had remained in it a considerable time.—*Gazette Médicale*, from the *Annales d'Oculistique*.

CLINICAL REMARKS

ON

CASES OF CHLOROSIS,

Delivered at St. Thomas's Hospital,

By DR. BARKER.

THE object of clinical lectures being to point out the application of the general principles of medicine, to the recognition and treatment of the ever varying forms, and complications of disease, rather than a constant consideration of extraordinary cases and cures, I need make no excuse for devoting a portion of this lecture to an account of three common cases of chlorosis, which have just left the hospital. These cases did not differ, in any essential points, from many others, which you will probably see in the wards during the course of the present winter; and my reason for thus early directing your attention to this class of cases, is, that you may be at no loss to know how they are to be recognised, and to understand the principles upon which the treatment you will see adopted, is founded, whenever such cases occur.

It is the more necessary to call your attention to these cases, because it is easy to mistake this disease for any others; and, even when the disease is recognised, it is seen under a great variety of forms; and is often, *apparently*, complicated with other serious affections. As you will not observe in my practice any difference, or even modification of treatment, corresponding to these various forms and apparent complications, you may, without some explanation, suppose that I am myself setting you the example of not following the rule so frequently dwelt upon in these lectures—that in the treatment of a disease you are not to regard its name, but must consider its stage, the actual condition of the diseased parts, and of the system generally, as well as the con-

stitution of the patients. Now, in chlorosis, the various forms it often assumes, and the many local diseases with which it often appears to be complicated, are generally dependent on one disordered state of system—when that is remedied, and not till then, the local disorders, and all the various complications, disappear; though, to an inexperienced or ignorant person, these complications and local disorders may, at first, have appeared the most formidable parts of, or even the whole disease, and to have merited the greatest share of attention. Moreover, the chance of error in recognising and treating cases of chlorosis, does not arise solely from the danger of considering its modifications and the various symptoms of local affection accompanying it, as principal features of the disease, demanding separate attention; but the real state of the patient—that is, the existence of the chlorotic condition—may be overlooked; and you may suppose it necessary to treat her for some other disease. The symptoms of which may appear to be more or less completely developed. Such a mistake will, in a large majority of cases, be productive of much injury; since the ordinary mode of treating such diseases as are most likely to be suspected when the chlorotic state is overlooked or disregarded, is, in nine cases out of ten, completely opposed to that which the state of the patient requires.

It is true, that in confirmed cases of chlorosis, there is little danger of the real nature of the disease being overlooked. The pallid, leaden, or pasty look of the face; the blanched lips; the pale tarsal conjunctivæ; the blue sclerotic; the dark hue of the skin beneath the eyes; the emaciation; the lost, or capricious and depraved appetite; the hectic which is often present; the disordered secretions, especially the menstrual; the headache, and various local pains, especially in the region of the heart; the languor and debility of body and mind; sufficiently point out the nature of the dis-

ease; and indicate a state of anæmia, with deficiency of the red and more nutritious parts of the blood: and many of the attendant symptoms—the debility, the languor, the headache, the palpitation, the imperfect menstruation—are directly referrible to this cause. But it is far otherwise when the disease is recent, or imperfectly developed: for, although most of the symptoms just enumerated may generally be detected from an early period, they are often so slight as to escape notice; they may exist without chlorosis; and symptoms of other disease, general or local, may be so prominent as to divert the practitioner's attention from the general state of the system; and fix it upon what is really, as regards diagnosis and treatment, an unimportant, though, to the patient, a most distressing part of the malady.

In the three following cases the general symptoms of chlorosis were sufficiently manifest; but were not likely to arrest the attention of an incautious practitioner, so immediately as the violent local pain in the head; the palpitation; and the unnatural sounds heard in the præcordial region, similar to those perceived in organic disease of the heart. Had my treatment been directed to these local symptoms, considering them apart from the general state of the system, my three patients, in place of being well and convalescent, would now be in a confirmed state of chlorosis, with every symptom of local disease increased.

The first case is that of Susan Neale, admitted September 29, æt. 20, a servant, who has never menstruated, though her bodily development does not appear imperfect. She dates her illness six months back; since which period she has become, without any positive disease, languid, and less strong than formerly; and during the last fortnight she has felt incapable of exertion. Since she first felt her health decline, she has suffered much from headache, palpitation, and pain in the chest. All the symptoms, slight at first, have gradually increased. At present she is pallid, with an unhealthy, pasty appearance of the face; the lips are blanched; and there is a dusky hue beneath the eyes. She seems languid; states that she is easily fatigued, and feels unequal to any exertion. She suffers much from headache, which is not constant. Any slight exertion, or mental emotion, causes instant palpitation of the heart; and this symptom often distresses her much when there is no apparent cause for it; frequently coming on in the night, or when she is quite at rest during the day time. The respiration is healthy over the whole chest: and, with the exception of greatly increased rapidity of breathing on slight exertion, there is no sign of disease of the lung. The heart can be heard over a large space, and

its impulse against the ribs is sudden and forcible. Over the aortic valves a loud and harsh bellows murmur accompanies each systole of the ventricle; which can be heard distinctly along the course of the aorta, and slightly over the apex of the heart. There is considerable tenderness on pressure of the præcordial region, but she also complains of some tenderness on pressure of other parts of the chest, and of the epigastrium and cæcum. Her appetite is not good; tongue clean; bowels regular; pulse frequent and sharp, but small, and bearing little pressure.

The next case is that of Mary Anne Chadwick, a servant, æt. 17, admitted into Anne's Ward, October 6, 1843. She had good health till four years ago, when she had an attack of fever, which confined her to bed for six or seven weeks; since which she has never completely regained her former health; and has remained pale and weak, suffering from short breath, palpitation, and headache. At the age of 16, the catamenia first appeared; the discharge being pale, but of sufficient quantity. They recurred monthly for four or five periods, and then ceased for four months. Under medical treatment, they returned four or five times; again ceased, and have not reappeared. The discharge gradually became paler and paler, before it ceased entirely. During the whole of this period, the breath had become more hurried on exertion; the pallor had increased, and the headache and palpitation had become more constant, and more distressing.

At the time of her first admission into the hospital, the whole surface was pale, and the countenance rather icteroid, with a dark areola round the eyes. Tongue pale and clean; appetite good, but depraved; bowels costive; pulse 114, small, sharp, but easily obliterated by pressure. Slight cough, and breathlessness on the least exertion; though, on careful examination of the chest, no disease of the lungs could be detected, the sound on percussion being clear, and the respiratory murmurs healthy and loud. The action of the heart was the same as in the last case; and a loud, but soft bruit could be heard over the aortic valves, and less distinctly over the whole præcordial region. Palpitation was easily excited, and often came on without any assignable cause.

The last case is that of Caroline Thacker, admitted into Anne's ward on the 24th October; a servant, aged 21. Her menstruation has never been quite regular in its periods, or proper in quantity or appearance. Five years ago she suffered so much from languor, aching of the limbs, debility, shortness of breath, fluttering of the heart, and pain in the left side, that she applied at Guy's Hospital for advice, and was much

relieved after a fortnight's attendance there. She has never, however, been quite free from the symptoms just mentioned; and three weeks ago, when, after exposure to wet, the menstruation was suppressed, they all recurred; accompanied with increased pain in the head and tenderness on the left side. For this, leeches were applied, and twelve ounces of blood were abstracted from the arm, with no relief to the general or local symptoms; and followed, the next day, by a hysterical fit, to which she had not previously been subject.

On admission, she was pale in the face and lips; rather dark under the eyes; complained of weakness, especially of aching pains in the loins and thighs after slight exertion; headache; tenderness in the præcordial region, and over the chest generally; a feeling of tightness under the sternum; shortness of breath, and fluttering of the heart easily excited. Appetite good. Bowels confined. Tongue pale, and clean. Respiration natural. Pulse quick, sharp, and feeble. There was a sharp, quick stroke of the heart; and, occasionally, a slight soft bellows murmur, accompanying the systole, could be heard.

There were several important points common to all these cases, indicating some generally depraved state of system; and there were other symptoms superadded, *appearing* to depend on local disease in the chest or head. Thus, in all, the disease had come on slowly, occupying many months, at least, in its invasion. There had been gradual loss of bodily and mental vigor; a certain degree of emaciation; increasing pallor of the countenance, shewn, not only in the cheeks, but in the lips, eyes, and tongue; and thus there could be little doubt that the blood had become, not only small in quantity, but deficient in red particles and other constituents. This state of the blood was further proved, in two of the cases, by the scantiness, pallor, and ultimately by the cessation, of the menses; whilst, in the other case, the same state might be inferred from the non-appearance, at the age of 20, of that secretion; although there did not appear to be any physical impediment to its production. Moreover, the feebleness and increased excitability of the vascular, and augmented sensibility of the nervous system, resembled, in all respects, that which takes place in anæmia, from whatever cause that state may be produced.

These patients were, in fact, all in an early stage of chlorosis; a stage which has been thus well described:—"Slight paleness, or a little fading of a wonted florid complexion, and the patient is only a little more languid and listless than usual, the ordinary amusements or occupations, whether mental or bodily, being accompanied

by fatigue; the nights restless, the mornings heavy; recurrent headache; pain in the left side, palpitation, &c. The catamenia *are supposed* to flow as usual, but an attentive inquiry discovers, that, with the complexion, the uterine discharges also lose their colour.

This is the first stage of chlorosis. In its second and confirmed stage, every symptom is aggravated, and the patient falls into a state of anæmia, with all its attendant evils. But, notwithstanding the urgent nature of the symptoms, and great constitutional derangement shown by the increasing pallor, and the unhealthy hue of the countenance; debility, often extreme; most distressing sensibility; emaciation; suppressed menses; lost or depraved appetite; irregularity of the bowels; and many other derangements; there is very frequently some predominant symptom, absorbing all the attention of the patient, and too frequently misleading the medical attendant. This symptom is generally severe pain, often fixed, though not unfrequently wandering from part to part. It most commonly affects the head; the left side, about the apex of the heart; or some part of the course of the colon; and, very frequently, gives rise to the idea that formidable local disease exists in those parts. This mistake is the more likely to occur when the pain is in the chest, and accompanied by cough and palpitation. These severe local pains, however, are by no means confined to the latter periods of the disease: they not unfrequently occur long before any of the general symptoms would lead you to suspect chlorosis. The risk of error is then great; and it is only by carefully considering the character of the pain, and finding all other symptoms of local inflammation wanting, that you can hope, in such cases, to avoid the error of having recourse to antiphlogistic treatment, which, after entirely failing to relieve the local evil, will inevitably promote the progress of the main disease.

It must be obvious that the first two of these cases were beyond the first stage, but had hardly completed the second; and that the last case (Thacker) was in the early stage. In all, however, there was the one predominant symptom absorbing the attention of the patient; and so far likely to delude the medical practitioner, that the mildest of the cases, the only one which had recently been under medical treatment, had evidently been mistaken for one of local inflammation; and had, under that belief, been bled and leeches. I pass over the headache noticed in all these cases; because, although it was severe, it was irregularly intermitting, and being unaccompanied by any other sign of cerebral affection, little danger existed of its being mistaken for inflammatory disease requiring depletory measures. But there were

signs of chest affection, especially of the heart, which might easily have misled the unwary. In the first place there was pain: but it was not the pain of any known inflammatory or organic disease of the chest. It was not the constant, dull pain of pneumonia, nor the more sharp and tight pain of bronchitis, nor the sudden acute pain of pleurisy; all, especially the latter, increased by cough or the movements of respiration; neither was it the severe pain of rheumatism, increased by pressure of the intercostal muscles, and becoming severe on any sudden movement of the trunk; nor was it the pain of cardiac disease, sometimes fixed, sometimes shooting to the spine, the shoulder, or left arm, and almost always increased by firm pressure; but it was a tenderness, rather than pain; sometimes felt principally in one part, and sometimes in another; not augmented by the movements of the patient; and although increased by pressure, pressure so slight that it could not possibly have produced any effect on internal parts, and scarcely any even on the intercostal muscles, caused as much pain as the most forcible pressure that could be made. There was, moreover, an absence of all other signs of any of these diseases, except the heart symptoms, to be alluded to directly; and this, together with the character of the pain, would in these, and may in most similar cases, enable you to avoid the error of mistaking such morbid sensibility for inflammatory or organic disease.

It is a peculiarity in chlorotic and hysterical cases, for which I cannot account, that the severe local pains, of which complaint is so frequently made, are very often referred principally to the heart. This circumstance often gives rise to the idea that the heart must be diseased, and leeches, blistering, &c. are had recourse to, without benefit, and too often to the great injury of the patient. In many of these cases, if the practitioner who makes such a mistake would ask himself what disease of the heart he is treating, he might avoid falling into a grievous error, and save his patient much useless and injurious treatment; for he would find that *pain alone*, whatever may be its seat or character, is no proof of *any* heart disease; and he would, by a careful examination of such cases, find that the pain, though often referred by the patient solely to the precordial region, is not really confined to that spot, but that other parts of the chest are, though perhaps in a less degree, tender on pressure.

The case becomes rather more difficult when, as in those now under consideration, there are, in addition to tenderness, other symptoms of diseased heart: increased impulse, palpitation, and abnormal sounds.

In all the three cases, though in different degrees, the stroke of the heart against the

ribs was so sudden and sharp, and accompanied by so loud and distinct a sound, that it was difficult, at first, to lay aside the idea of the heart being increased in size, and its contractions stronger than natural; but more careful examination shewed that the parietes of the chest were not moved by the heart's impulse, that there was not a long-continued heaving over the heart, during the whole of the systole, and that the sound was not dull, or confined to a small space, as is invariably the case in hypertrophy. On the contrary, the sudden, sharp stroke felt at each systole, did not perceptibly move the hand or the head when applied to the region of the heart; the slight impulse which could be felt was momentary, and only felt at the apex; and the sound was loud, clear, and heard over a large space, although there was no consolidation of the lung to convey it to a distance. Percussion proved that the heart did not occupy more than its ordinary space. The pulse also, though frequent and sharp, was small and feeble, not full and strong, as in cases of hypertrophy. Finally, the impulse of the heart, the loudness of its sound, the frequency and strength of the pulse, were greatly, and much more easily than is usual in hypertrophy, varied by the position of the patient, by bodily exertion, or by slight mental emotion.

Palpitation was another of the symptoms, present in all these cases, which may exist both in functional derangement and organic disease of the heart. But, in organic disease, the palpitation is either constant, or, when it comes on in paroxysms, is referrible to some cause: in nervous palpitation, whilst bodily exertion and mental emotion often bring it on, it as often comes and goes without any assignable cause; absent, perhaps, when the patient is taking gentle exercise, and has the mind moderately excited; coming on when she is quiet and at rest. A due attention to these differences, and the absence of all other proofs of organic disease, will enable you to avoid any error which might arise from mistaking nervous palpitation for that which attends other disease of the heart.

But bellows murmurs were heard in all these cases; in two of them very loud and constant, differing in no respect from those which are heard when there is disease of the aortic valves obstructing the flow of blood from the ventricle. I shall not inquire now what is the immediate cause of bellows murmurs accompanying functional disease of the heart. That they do exist, without disease of the valves, must be admitted, and I know of no peculiarity, in the seat and nature of the sounds, by which we can distinguish those arising from organic disease from those which have some other, and that a

temporary origin. The only rule, as regards the sound itself, which I can give you, is, that it is seldom harsh; (it was so, however, in the case of Susan Neal;) so that if you hear a rasping or sawing sound, it is more likely to arise from organic than from functional disease; and, in functional disease, the sound is always systolic. It is principally, then, by a consideration of other points, that we must determine to what cause these sounds are to be ascribed. If they are permanent in their seat and intensity; if they are accompanied by other signs of diseased valves, such as hypertrophy, dilatation, &c.; if the palpitation, when present, partakes more of the character of that attending organic than of that arising from functional disease; we may feel sure the valves are diseased. If, on the other hand, there be the general symptoms of hysteria, or chlorosis; if there be no signs of hypertrophy or dilatation of the heart; if the sounds vary in the position where they can be best heard, and in their loudness and character; we may feel pretty sure that no organic disease exists. This latter sign of the disease being functional is often very remarkable; and was observed, sooner or later, and in different degrees, in all three cases. The bellows sound may be loud one day, faint, or not perceivable, the next, and then return; it may be absent when you commence examining the chest, but become evident before you have finished: a little excitement, or slight bodily exercise, will sometimes cause it to disappear and sometimes cause it to return. Many of you must have noticed this in Chadwick and Thacker.

In estimating the value of these various modes of distinguishing between organic and functional disease of the heart, it is plain that some of them may be appreciated at the first examination of a patient, whilst others can only be made use of, for the purposes of diagnosis, after repeated visits. Hence, it may often be necessary to delay giving a decided opinion as to the nature of a case: circumstances may make us think one or other form of disease most probable; but, if our opinion is given too hurriedly, we may, ere long, be compelled to retract it. In the cases now before you, we could at once detect that the heart was not much larger than natural; that the impulse was not that of hypertrophy; and in two, Chadwick and Thacker, the mode in which the disease came on; their general appearance; the character of the pain and palpitation; the absence of all *positive* signs of heart disease; the kind of impulse, sound, and pulse; sufficiently proved the nature of the case. There was more difficulty, however, in the case of Neal; for, whilst many of her symptoms were merely slight modifications of

those observed in the others, the impulse of the heart was not very unlike the heaving observed in hypertrophy of that organ; and the loud, harsh sound, accompanying the systole, heard over the aortic valves, and extending along the arch of the aorta, had far more of the character of the sound which *usually* attends diseased valves, than that which *usually* attends functional disease; besides which it was permanent, and unaltered for many days. I should have been in great danger of doubting in this case, had I not recently had under my care a young person, with similar sounds, which were even more permanent than in Neal. She had general symptoms of chlorosis, and I treated the case as such; but no change took place in the impulse or sounds of the heart, for more than three weeks. I was beginning to express doubts as to the correctness of my opinion, and feared the case was one of diseased valves as well as chlorosis, when improvement began to take place; the countenance regained its healthy appearance; and, at the same time, the sounds of the heart gradually resumed their natural character.

Bearing this case in mind, and considering all Neal's symptoms, I felt little hesitation in classing her with the other two—chlorosis was the disease in all. It was from the first evident that the symptoms of heart disease were fallacious in two; so probably in all. The same treatment was adopted for all: meat diet, or milk and farinaceous diet, according to the wish of the patient; the only one who chose the latter, soon asked for meat. The medicine for all was quinine, sulphate of iron, and a few drops of sulphuric acid, in peppermint water. This was continued till they left the hospital: Neal on Oct. 24th; Chadwick on Oct. 31; and Thacker on Nov. 12. The latter had omitted her medicine for a week, immediately after it was commenced, in consequence of a severe cold. In every case some amendment was perceptible soon after the iron was commenced. The countenance assumed a more healthy colour; the pulse became stronger, whilst it diminished in frequency; the bodily strength increased; the patients expressed themselves as feeling better; the appetite became more natural; and an improvement took place in the action and sounds of the heart. This improvement was not equally rapid in all; and in none did it continue without occasional checks—the pain, palpitation, &c. sometimes increasing. All had recovered their healthy appearance, to a great extent, before they left; were free from local pain; and had neither palpitation nor abnormal sounds of the heart. They would all have been kept longer in the hospital, had not one been obliged to leave; and the others had an opportunity of going

into the country, where they could continue the use of medicine, giving them a better chance of complete and permanent recovery than if they had remained confined closely to the wards of an hospital.

Before concluding, I must call your attention to one important feature of chlorosis, well illustrated in these cases. They all, after great improvement in every other respect, continued to complain of headache, and tenderness about the chest, especially at the left side. Whilst every other part of the malady is rapidly disappearing, the local pains very frequently remain, little, if at all, diminished, and do not disappear till the patient is quite convalescent in all other respects. When this was the case I formerly thought it useful to apply blisters, and even a very few leeches; but now, unless the chlorotic condition be slightly developed, and the pain very severe; or, unless it be absolutely necessary to do something to satisfy the patient; I rarely have recourse to such means; being convinced that, in a large majority of cases, they are not required.

I will conclude by a question—These cases rapidly became convalescent whilst using good diet, iron, and quinine: what, then, must have been the consequence had they been bled, leeches, blistered, purged, and salivated, under the impression that they were affected with disease of the heart or pericardium, pleurisy, or chronic meningitis? Such practice is sometimes followed in consequence of these mistakes; and we occasionally see the results in the pallid, exsanguineous, nervous, and debilitated creatures who are admitted into the wards.

THE NEW FORM OF FEVER AT PRESENT PREVALENT IN SCOTLAND.

AN ACCOUNT OF THE GLASGOW EPIDEMIC.

By WILLIAM REID, Surgeon, Glasgow.

(For the Medical Gazette.)

ABOUT twelve months ago, a form of fever made its appearance in Glasgow, which, in its progress, presented phenomena totally different from any epidemic of this disease, and whose symptoms and duration contrasted strongly with typhus, to which that city is constantly subject. My attention was first attracted to it, towards the end of January of the present year, by being called to visit individuals who had been discharged convalescent from our excellently conducted Fever Hospital. Scattered cases, gradually increasing, occurred in February, March, April,

and May; but during the five following months these multiplied to an extent unparalleled in the history of diseases of this country—ten times outnumbering the cases of cholera in its worst days. Under certain predisposing circumstances, it spread with unexampled rapidity, attacking every member of a family in quick succession, so that, notwithstanding the short course of the disease, five to ten patients were frequently seen at one time, and in a single apartment, huddled together in the different stages of the malady. It will scarcely be credited, that in one tenement, separated from other buildings, but most numerous inhabited, upwards of one hundred victims were affected in less than three months. I am certain, however, from information derived from the surgeon of the district, that this statement, if incorrect, errs not on the side of exaggeration.

The symptoms of this febrile disorder are universally ushered in by rigors, whose intensity and suddenness determine the character of the attack. The patient, for the most part, is then immediately confined to bed; he often vomits a considerable quantity of bilious fluid; always complains of pain in the head, back, and extremities—the first especially being of a most constant and aggravated description. The prostration of the animal powers is most overwhelming, and is usually accompanied by despondency of mind. The thirst is very urgent, and no sleep is obtained until the crisis of the disease, unless it be artificially induced. The pulse ranges from 100 to 120, seldom lower than the former, though frequently rising ten or twenty beats above the latter number towards the subsidence of the disease, when it loses its strength and fulness, and sinks to an alarming extent. Tongue is coated with a thick white or yellow fur, through which the florid papillæ sometimes appear, especially towards the tip and edges. Occasionally, when hæmorrhage occurred, or when the crop of purple petechiæ was copious, the tongue became brown or black, and sordes collected on the teeth and lips. The skin, for four or five days, is generally hot and dry; after which spontaneous diaphoresis often leads to a favourable termination. The bowels are for the most part constipated.

These are the symptoms of a well-

marked case, but these alone would not enable us to distinguish between this fever and typhoid or continued fevers. The short duration of the disease, and the sudden transition from violent excitement to a regular pulse and a cool skin, are, however, so astonishing and unexpected, as at once to determine its character. The disease runs its course in from five to seven days—never in my practice terminating earlier than the fourth, or continuing longer than the eighth day. The crisis is generally preceded by copious perspiration; in some cases this obtains to an excessive degree, and is introduced by shivering. I have often seen a patient in this state—lying on back with livid and anxious face; eyes sunk, glassy, and injected; voice hoarse, and barely audible; extremities cold; and the whole surface covered with clammy sweat, saturating the bed-clothes with moisture. Here, so overpowering were the sense and appearance of exhaustion, that, but for a knowledge of the history of the prevailing epidemic, the patient would have been declared moribund. After a short struggle the poison seemed banished from the system, and convalescence slowly ensued.

Although these may be considered the most prominent and constant features of the disease, there are several occasional concomitants and consequences, which I will briefly notice according to the frequency of their occurrence.

The most remarkable and invariable circumstance connected with this form of fever is its tendency to relapse. Dr. D. Craigie, in his account of the epidemic as it prevailed in Edinburgh, graphically detailed in the October number of the *Edin. Med. and Surg. Journal*, states, that, of his patients, 110 relapses occurred out of 182 cases—equivalent to 60½ per cent. In Glasgow the proportion is very different. Here it is considered an exception to the general rule if the disease do not recur. Five per cent. of my own patients did not escape a second attack; which, unlike the same occurrence in common fever, supervened independently of atmospheric exposure or errors of diet. The interval generally occupies the same number of days as the preceding attack. Ten or twelve days, however, sometimes

intervene; and in one case mentioned to me by a medical friend, the interval was extended to the twentieth day. A chill is then felt, and the disease again sets in; usually, however, of a milder character, and shorter by a day than the former attack. Occasionally in infancy, or where the patient had been previously affected by some chronic complaint, the relapse occurs a second or even a third time. Unlike Dr. Craigie, I have seldom or never found the tongue become clean, or the appetite keen, after the pyrexia; on the contrary, the tongue continued foul, and an actual loathing of food was often present, and persisted in spite of all remedies exhibited. Indeed, the inertia of the stomach during convalescence seemed to me to be the most strongly marked characteristic of the disease.

Towards the close of the first attack, in the intermissions, and during the recurrence, there exists a great tendency to discharge of blood from the mucous surfaces. I seldom found these to produce any relief to the patient, or to retard his recovery, although several pounds of blood frequently escaped, especially from the nose or bowels. In one girl aged 14 years, of stunted growth and unhealthy aspect, it proved fatal during convalescence after a first attack. In the forenoon of 20th June, she menstruated for the first time; about an hour afterwards she became sick, stupid, and vomited a large quantity of clotted blood. She then had a similar evacuation from the bowels with syncope: and when visited at mid-day, I found her dead on the floor. A few drops of blood had oozed from the left ear. The presence of this fever, like the sweating fever of Normandy, exerts a most powerful influence on the uterine system. It is almost always accompanied by profuse menstruation, and if the patient be pregnant it most certainly induces abortion or premature labour; in the latter case the child dies.

Yellowness of skin, with or without irritation of stomach depending on biliary derangement, is often to be met with. The discolouration in some cases extends over the whole cutaneous surface, beginning at the temples, equal in intensity to the worst forms of jaundice; in all the skin retains a dingy paleness for weeks after the cessation of the

fever. According to my experience this complication did not add to the danger of the patient, though in hospital practice I understand it frequently led to a fatal termination.

Articular rheumatism, various in degree, delirium chiefly of a hysterical character, and diarrhœa with copious bloody stools, are not uncommon symptoms. These usually occur in the intermission, and are speedily removed by opiates in the form of P. Doveri. In some rare instances we find anasarca affecting the lower extremities, with pain and fulness in the region of the liver and spleen.

It has been frequently proved by the statistics of typhoid fever, that the period of life determines the liability to an attack, and likewise its mortality. It spares the extremes of life; but when it seizes an aged victim a fatal termination may always be predicted. In this respect the present epidemic offers a striking contrast. It displays no partiality for particular ages, embracing the newly-born child, and the old man on the verge of the grave, as readily as the young and the middle-aged. I lately saw an infant eight days after birth studded with purple petechiæ, and a woman in her 84th year, presenting exactly the same appearance. Most providentially the mortality produced by the disease was trifling, and almost altogether confined to children under two years of age, or persons who were otherwise constitutionally unsound.

Is this form of fever contagious? When a disease prevails extensively in particular districts, and simultaneously affects subjects of a particular class, it is sometimes difficult to determine whether the prevalence is produced by contact with the sick, and exposure to the effluvia generated by them, or depends upon some unappreciable constitution of the atmosphere arising from local or general causes. *Individual* cases of suspected contagion, however strong and carefully detailed, can never furnish conclusive evidence of the fact; but when these instances *multiply*, and occur under various circumstances, doubt is thereby changed into certainty, and we are fairly entitled to adduce such accumulation as unquestionable proof of the communicability of a disease depending on intercourse with the sick. Numerous opportunities of

thus testing the contagious nature of the present epidemic have presented themselves during its progress through the lanes and closes of this city and suburbs. A few illustrations may be given, but, it must be borne in mind, that *almost every medical man* actively engaged in the treatment of the epidemic *could also enumerate examples of the same description.*

When for the first time a person was attacked in a house or district, the disease radiated from him, and that too in exact proportion as the communication between the healthy and sick was more frequent, close, and intimate. In the densely populated parts of the city, occupied by the lowest order of the working classes, two or more families frequently inhabit the same dwelling. When the disease appeared in one apartment it first attacked all its occupants; then spread to the room adjacent, and afterwards sought its victims in the rooms on the same floor in the order of vicinity and intercourse. The manner of its introduction and propagation among the numerous families at Dalmarnock colliery is a case in point, and deserves to be recorded, as furnishing—to say the least of it—a very strong probability of the operation of contagion. Forty families occupy a large tenement of three stories entered by three separate stairs. The building stands alone and is surrounded on every side by open fields. At last Whitsunday term an Irish family removed to a single apartment on the upmost flat reached by the middle stair; the youngest child was at that time sick of the fever. On the 2d June the father sickened, and in succession the whole family. It then spread from house to house, and ultimately descending a stair, settled for a time, having in the space of two months attacked 22 patients. The supporters of malaria as the origin of the disease may doubtless here aver that the removal of the patient and the appearance of the fever in a locality previously healthy, were merely accidental; but I suspect they will find few with faith sufficient to believe in so curious a coincidence. Again, the disease was introduced by a person from a neighbouring village into a house of two apartments, situated in Mile-end, and containing within its narrow walls eleven human beings. All of these were attacked, and every

one relapsed; but in the next house, with a similar entry, and separated only by a brick partition, where the occupants were nearly equally numerous, and from their circumstances and habits equally susceptible, all escaped. Now if contagion was not here the agent in operation, but a vitiated state of the atmosphere from some unknown cause, or from local telluric emanations, why were the ravages of the fever confined to this dwelling only; and why did its baneful influence not extend to the adjoining house, and to others around it? Moreover, during the progress of the fever in Glasgow several of the medical attendants have been seized by it, and I understand that in the Fever Hospital most of the medical clerks who reside in the house, and the sick nurses, have also suffered severely from attacks of the disease.

Although I think that contagion is the mode by which this febrile disorder is mainly propagated, and is perhaps its imported source, there are several circumstances which undoubtedly favour the diffusion of the disease, or increase its communicability by predisposing the patient for its reception. The most prominent and prevailing of these are impure air, want of, and impure, water, scarcity of food, and deficiency of clothing. In Glasgow the combination of these powerful influences in the extension of all contagious diseases seems to be considered the natural birthright of poverty, as long-sustained exertions are seldom employed to ameliorate or remove such frightful sources of physical suffering, and its almost universal companion, social degradation. The crowded abodes of the working population, and especially of the poor, are almost universally built without regard to ventilation, and, from the neglect of sewerage, are generally damp, and consequently filthy. A number of *hydropathic* societies have lately been formed in Scotland; and I do most certainly expect much good to result from the exertions of their members. If they be the means of impressing upon the minds of the inhabitants the importance of the frequent and ample use of cold water, externally and internally, for health and comfort, they will have conferred an incalculable amount of benefit on the community. I would, however, respectfully suggest, for the consideration of these societies,

the oft-repeated axiom in cookery, "to catch the hare," before proceeding further in the operations of the kitchen. Let them see that the supply of water is pure and abundant, and that blankets are plentiful, and I promise them that their efforts will be eminently successful, if not in curing disease, at least in preventing its extension, by increasing the bodily vigour and the mental activity of the poor. The supply of water for the large towns of the United Kingdom, where, from the congregation of multitudes, a profusion of it is most requisite, is notoriously deficient; and it would be a subject not altogether unprofitable, for one curious in statistical inquiry, to determine how many tons of mud the inhabitants of Glasgow annually drink. Added to this, the wells, at least in the suburbs, are frequently placed in the streets at a distance from the houses of the poor water-rate payers, who are thus naturally led to an economy of this essential element in their domestic and detergent occupations: besides, a still more crying evil results from this disposition of the wells; a stream of running water is thereby denied to the closes and courts, &c.: thus the only means of perfectly removing the stagnant pools of contaminating accumulations cannot be obtained but at increased expenditure of time and labour.

Dr. Craigie seems disposed to regard the disease as a variety of remittent fever, he having frequently observed, in Edinburgh, a tendency to a remission of the symptoms on particular days. My experience, which has been but too extensive, is directly opposed to this opinion. I, without exception, have found the symptoms most continued — far more so even than in typhus, where we often find a diminution of the excitement in the morning, with an exacerbation towards evening.

In our treatment of this epidemic we have derived very little advantage from following the *methodus medendi* of typhoid or synchoid fevers. In these the early exhibition of an emetic, followed by a free purge, frequently seems to arrest the progress of the complaint, or at least to moderate the violence of the symptoms; and this more particularly where the stomach is loaded with *injeta*, or where exposure to cold may be suspected as the exciting cause of the fever. Here,

notwithstanding the clear evidence of biliary derangement, and consequent gastric irritation, an emetic never checked the course of the disease; and even the immediate improvement was very evanescent. Indeed, the beneficial effects produced by the administration of medicine, at the commencement, and during the first three or four days of the disease, were far from satisfactory; the patient, at each visit, having some new source of ailment to add to his irritability of temper, depending on his constant wakefulness. Our treatment principally consisted, at the onset of the disease, of mild emetics, with purgatives containing calomel; and towards the close, of opiates at bed-time. A full dose of muriate of morphia, combined with antimony, or Dover's powder, seldom failed to induce sleep and relieve the headache, which seemed to be often neuralgic, and sympathetically present from an excess of acrid bile in the primæ viæ. The complications of rheumatism and diarrhœa during convalescence were quickly removed by the same means. Delirium also, which in some rare instances supervened in the intermission, readily yielded to the same treatment, or to the exhibition of a couple of drachms of the morphia solution by the rectum. This soothing treatment was most grateful to the patient, who seldom failed to urge his medical attendant to a repetition of the medicine. Leeches to the temples very seldom produced much relief to the pain of the head; and the sense of debility was so overpowering as to lead to caution in the use of the lancet. After watching the effects of large spontaneous hæmorrhages upon the system, and observing that the debility was never thereby augmented, but sometimes lessened, I tried venesection in sound constitutions. The crassamentum of the blood was always firm, cupped on its surface, and covered with a thick firm pellicle of lymph; but the benefit derived from the adoption of the practice was not such as might have been expected from the inflammatory character of the blood. Two male patients presented, during recovery, most violent maniacal symptoms, and were successfully treated by repeated blisters to the head, and mercurials.

In the interval various medicines were prescribed, with the hope of

preventing a recurrence of the disorder. Alteratives, with quinine, iodine, and iron, were unsuccessfully used. Within the last month I have ordered the arsenical solution with this intention, and occasionally with *seeming* success; it is, however, more than probable that this partial success depended on the reduction of the temperature of the weather which then set in. The medicine, besides, can only be fairly tested in hospital practice.

15, Orr Street, Glasgow,
Nov. 20th, 1843.

CONTRIBUTIONS
TO THE
PHYSIOLOGY OF THE HUMAN
OVARY.

By CHARLES RITCHIE, M.D. Glasgow.
(*For the Medical Gazette.*)

THE following dissections were made by the writer during the last three years and a half, while he occupied the physicianship of the Royal Infirmary, and the notices of them were engrossed in a common-place book at the time. In undertaking the investigation, he was influenced only by a desire to avail himself of the advantages of his position in regard to a subject having a physiological, and, in its relations to jurisprudence, a moral interest of no ordinary kind. No one can be more sensible than he is, how far, from the pressure of more urgent avocations, and other causes, he has fallen short of his object; and in submitting his researches to the profession, when from circumstances he cannot longer continue them with the same facilities, he is influenced rather by a wish to suggest the subject, under some modifications of form, to others, than by any notion that, in his hands, the inquiry has been exhausted. The paper has been arranged into a detail of cases and a summary; the former being subdivided into two parts, and each of these respectively into several sections as follows:—

PART I.—Dissections of the human ovary in cases in which impregnation had never obtained.

II.—Ditto in individuals who had been pregnant, the ovaries being examined at different periods of uterogestation, or, after delivery.

Under Part I. are examined

SECTION I.—Ovaries in subjects which had not menstruated.

II.—Cases in which menstruation had existed regularly, the parties never having been pregnant.

III.—Cases in which menstruation, although commenced, had never been regularly established, the individuals not having had children.

IV.—Cases in which menstruation had continued regular for a longer or shorter period, but had been suppressed for some time before death, the women never having had children.

V.—Cases in which the subjects had outlived the menstruating period of life without children.

Under Part II. are examined

1. Ovaries of parties either supposed or really pregnant, examined before the completion of gestation.

2. Ovaries of women who died within one month after delivery at the full period.

3. Ovaries of women who died within, or at, two months after delivery at the natural period.

4. Ovaries of women dying from two to three months after delivery at the natural term.

5. Ovaries in individuals dying four months after natural delivery.

6. Ovaries in women five, six, seven, ten, twelve, and thirty-six months respectively after natural delivery, menstruation not having been re-established.

7. Ovaries in subjects who had had children, but were afterwards menstruating.

8. Ovaries in individuals who had had children, and in whom menstruation, re-established, had been arrested by disease.

9. Ovaries in persons who had had children, and who had ceased to menstruate from age.

PART I.—Dissections of the human ovary in cases in which impregnation had never obtained.

I.—Ovaries in subjects which had not menstruated.

1. A healthy new-born infant at full time. Fallopian tubes and uterus could not be permeated by air, but on examining the os uteri it was found occupied by a plug of thick tenacious mucus, of the colour and consistence of glue, which also filled the uterine cavity, dilating the former to a size equalling that of the tip of the little finger, and permitting the arborescent structure of

the cervix to become visible. On removing this mucus, which was effected with difficulty, the last portions being tinged with blood, air was made to pass with ease from the pavillon of one of the tubes to the os tincæ. Ovaries scarce an inch in length, or two-eighths broad, of a triangular shape, the apex being represented by the free mesial line of the gland, and the base by its sessile portion expanded on each side into a loose margin, which was denticulated by several notches. Outer surface of ovaries smooth, and of a uniform fawn colour, and in interior of one of them two vesicles were distinguished.

2. An infant sixteen weeks old. Fallopian tubes transmitted air with great facility. Right ovary one inch in length, and two-eighths of an inch in breadth at centre. Left ovary seven-eighths long, by two and a half broad. No foramen or cicatrix could be detected on their external surface, which was observed by means of a simple magnifier, however, to be occupied every where with the appearance of minute pores, aggregated at some parts into indentations, visible to the naked eye. On boiling, and then cutting the glands vertically, their interior, especially that of one, was found thickly studded with extremely delicate vesicles, filled with a milky fluid, varying in size from that of a pin's head to a mere point, and which became speedily flaccid, and finally disappeared on exposure to the atmosphere, apparently from absorption of their contents.

3. — Goulden, aged $5\frac{1}{2}$ years. Fallopian tubes pervious to air and quicksilver. One ovary one inch and a quarter long, and two and a half eighths of an inch broad, and the other thirteen lines in length, and two and a half eighths in breadth. On one of these a transparent spot was observable, which, when viewed by a common two-inch glass, was found to be a very delicate diaphanous vesicle, of the size, when thus magnified, of a mustard-seed, and surrounded at its base with an opaque or white ring. Immediately adjacent to this was a dark spot of the supposed diameter of less than a line, which examined by the magnifier, seemed to consist of a central puncture surrounded by ecchymosis. Several other copper-coloured spots, in one no less than six, were observed in both ovaries, but without the

central opening. These appeared to be occasioned by Graafian vesicles, with their coats in a high state of vascularity shining through the peritoneal covering of the glands. In other respects surface of ovaries smooth. On boiling one of the ovaries, and dividing it vertically at its centre, seven or eight vesicles came into view in different parts of the gland. The best developed were situated almost immediately under the peritoneal coat. One of the largest was of the size of a mustard-seed, had an opaque capsule, and contained an angular-shaped, reddish-coloured coagulum. The capsule of another was of a brick-red colour, and contained a coagulum which was of a lighter shade in its central part, but surrounded by a delicate disc of what appeared to be dark-coloured blood.

4. — —, æt. 13 years. Ovaries one and a half inch long. Surface free from any solution of continuity, but studded with numerous vascular spots of size of coriander seeds, which were produced by Graafian follicles situated at varying depths from surface; some adherent to inner aspect of peritoneal covering, and others projecting this membrane before them into a small elevation, over which the peritoneum was thinned and vascular. One of these vesicles insulated and examined by a powerful microscope, exhibited a number of such vessels ramifying on its surface, and in its interior, the ovulum adherent to the proligerous disc, and containing at the point at which it was thus in contact, the vesicle of Purkinje. The granular nature of the fluid of the Graafian vesicle was also observed. The ulcer, of the size which it is in the infant, contained a starchy-looking fluid.

5. — —, æt. 14. Surfaces of ovaries presented numerous livid points produced by Graafian vesicles shining through the peritoneal coat, and some capillary openings were observed at different parts. These latter did not permit of the transmission of a bristle by them into the gland, or lead into any cavity, but were mere points limited to the external aspect of peritoneal covering, and no cicatrices such as are found in the adult, were observable anywhere. Interior of ovaries filled with ovisacs of a very minute size, the largest not greater than a pin-head. Some of these were very near the surface, covered with an indusium of the ovary, and under their

outer proper coat beautifully injected with red vessels. The fluid contained in them was of a rich amber colour. The fallopian tubes were filled with white mucus.

6. — —, æt. 14. Ovaries of medium adult size and plumpness, but without a wrinkle, cicatrix, fissure, or any thing remarkable on their surface, except three minute spots, two on one of the glands, and one on the other, which appeared to be Graafian vesicles situated behind or in the texture of the peritoneal coat, and one of them, which to the naked eye was not larger than one third of the size of a pin-head, was apparently a projection through the peritoneum of a segment of the vesicle, its base being surrounded, as seen by a common magnifier, with an opaque ring. Interior of ovaries surcharged with vesicles, one of them as large as a small raisin, the others varying from the size of a hemp-seed to that of those on the surface. These latter were full of fluid, but their coats seemed less vascular and more attenuated than those of the others. No vestige of any vesicle having ever been ruptured was perceptible.

7. — —, æt. 15 years. Ovaries of adult size: one of them in particular had its surface stained with numerous whitish points of size of millet-seeds, which were found to proceed from Graafian vesicles shining through peritoneal covering. This latter was completely destitute of cicatrices, except in one of the ovaries, on which was observed one point, best seen with a magnifier, which appeared to consist of a minute foramen, having its edges of a slightly red colour. Inner surface of both ovaries occupied by the usual membranous pulp of considerable thickness, and giving the idea of a series of horizontal layers of fine tissue, each thickly interspersed with vesicles of different sizes and grades of development, embedded or suspended in its structure. Some of these had advanced, seemingly by a gradual progression from the central parts of the gland, about half way through the peritoneal coat, and one of them opened by a rather blunt lancet, with no more pressure applied to the surface of the ovary than was necessary for its retention between the fingers, squirted its contents a distance of about twelve inches.

8. ———, 16 years of age, and never menstruated, although her general and uterine systems well developed. Ovaries large, and studded with blue spots about the size of corns of barley, which corresponded with Graafian vesicles, with which both glands were filled. No cicatrices or wrinkles of any kind on surface.

This girl appeared to have been a prostitute. The genitals were ulcerated, and a vesicle filled with lymph, of about the size of a Spanish nut, hung from the pavillon of left fallopian tube.

9. ———, æt. 17½ years. Had not menstruated or had a child. Health delicate, and labia of uterus granulated. Both ovaries plump, of good size, perfectly smooth, and exhibiting a few minute mahogany-coloured spots on exterior. Internally they were filled with vesicles, many of them as large as small dried peas; some of which were vascular, although the greatest number were pale and somewhat flaccid. No traces of a rupture in any case in which it could not be ascertained positively that menstruation had not taken place, but inferentially only, from the circumstance not being noted in the usual way in the register.

10. ——— Martin, æt. 19. A prostitute. Had not had a child, as judged of by register, by absence of lineæ albicantes on mammae, thighs, or abdomen; by fact of os uteri retaining its normal form as seen previous to parturition. Some adhesions around ovaries; the outer aspect of both of which latter was smooth and free from cicatrices. Some vesicles of size of a hemp-seed, with vascular coats, were observed in the central parts of both ovaries, while more laterally, and immediately under the peritoneal coat, they were smaller, their tissues pale, and over some of them a minute blister was observed in the periphery of the ovary, and in others the appearance of capillary puncta, one of which actually led into an empty Graafian vesicle situated in the peritoneal covering of the gland, of about the size of a mustard-seed, and was surrounded by some appearance of ecchymosis.

[To be continued.]

THE PHYSIOLOGY OF THE LARYNGEAL NERVES,

ILLUSTRATED BY PHENOMENA OBSERVED IN
A CASE OF ANEURISM OF THE ARCH OF
THE AORTA.

To the Editor of the Medical Gazette.

SIR,

HE who watches the effects of disease is enabled occasionally to throw some light upon the labours of him who observes the operations of health. The student of pathology is now and then presented with facts, which afford considerable support to the inferences deduced by physiological experimenters; and when he is in the possession of such facts it becomes his duty to make them known for the interests of science, and the gratification of its cultivators. Under this impression I will endeavour to relate, as shortly as possible, some particulars of a case of aneurism of the aorta, (recently under the care of Dr. Gordon, in the London Hospital) which bears upon the functions of the superior and inferior laryngeal nerves, as investigated and ascertained by Dr. J. Reid.

During the progress of the disease in the patient already alluded to, some phenomena presented themselves not unusually remarked as the consequence of the gradual enlargement of an aneurismal tumor in the chest. Of these, a most marked alteration in the strength and pitch of the voice, and the occasional occurrence of paroxysms of suffocative dyspnoea, were the symptoms which denoted an interference with the due performance of the functions of the larynx.

The alterations in the voice, from what was manly and deep-toned to a squeaking whisper, must have depended upon a narrowing of the glottis, and a stretching of the vocal ligaments,—a condition which could only arise from the predominating influence of only one set of muscles. This influence must have been exerted by the crico-thyroid and sterno-thyroid, since the effect of their contraction is to produce a tension of the chordæ vocales by depressing the front of the thyroid cartilage on the cricoid; and if their actions were perfect, their supply of nervous energy must have been normal; while as

theremaining muscles of the larynx were in a semi-paralytic state, so must their due amount of nervous supply have been in some way or other impeded. It has been proved by the experiments of Dr. J. Reid, that the application of a stimulus to the superior laryngeal nerve merely produces the contraction of one muscle, the crico-thyroid; and that irritation of the inferior laryngeal nerve produces contractions of all the other muscles of the larynx,—facts which are in accordance with the ultimate distribution of these nerves. From a consideration of these circumstances, it was diagnosticated in the case which forms the subject of the present communication, that the recurrent laryngeal nerve was implicated by the progress of the aneurismal sac, and it was inferred that in this way the action of all the muscles of the larynx, except the crico-thyroid, was interfered with.

The occasional occurrence of paroxysms of suffocative dyspnœa was brought on sometimes by the effort to speak, and at others by the attempt to take nourishment more hurriedly than usual. That the dyspnœa was not caused by pressure upon the trachea and narrowing of its calibre, was evident, from the difficulty of breathing being paroxysmal, whereas if the cause had been permanent, the effect must have been equally constant. Here, again, the researches of Dr. J. Reid furnish a satisfactory explanation of the phenomenon in question. The following passage, extracted from Dr. Carpenter's *Physiology*, p. 140, will exhibit in a few words the results arrived at by Dr. Reid. "It has been ascertained by Dr. R. that if the inferior laryngeal branches be divided, or the trunk of the par vagum be cut above their origin from it, there is no constriction of the glottis, but a paralysed state of its muscles. After the first paroxysm occasioned by the operation, a period of quiescence and freedom of dyspnœa often supervenes, the respirations being performed with ease so long as the animal remains at rest; but an unusual respiratory movement, such as occurs at the commencement of a struggle, induces immediate symptoms of suffocation, the current of air carrying inwards the arytenoid cartilages, which are rendered passive by the paralysed state of their muscles; and these falling upon the opening of the glottis like

valves, obstruct the entrance of air into the lungs." From these facts it might have been again inferred, that in the instance before us, the superior laryngeal or afferent nerve of the larynx was perfectly sound, and carried on its excitor functions with precision; and that the inferior laryngeal or efferent nerve was pressed upon by the aneurism, and in this manner had its anterior motor functions obstructed.

The bursting of the aneurism into the left pleura caused the immediate death of the patient. On a *post-mortem* examination it was found that the sac consisted of a dilatation of the arch of the aorta in its latter two-thirds, and chiefly along its convex border. The aneurismal tumor was very large, extending upwards and to the left side to within two inches of the left lobe of the thyroid body, and capable of containing about a pint and a half of blood. It was closely adherent to the trachea and œsophagus, without pressing on them at all. The condition of the inferior laryngeal nerve is thus described in the *post-mortem* case-book. "The left recurrent laryngeal nerve had, of course, to wind round the whole bulk of the aneurism, and in so doing was condensed, hard, red, inflamed, involved in the condensed tissue around the aneurism, and at its posterior part flattened out, its fibres separated, and apparently wholly disorganised." Such was the natural condition of the left motor nerve of the larynx, a state fully adequate to destroy the balance between the muscular movements of that organ, and to give rise to those remarkable symptoms which have been detailed above.

The insertion of this communication in your journal will greatly oblige

Your obedient servant,

F. G. JACKSON.

CASES OF HYSTERIA.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH several years have elapsed since the following cases occurred, their interest is by no means diminished in consequence, and I think they merit a more prominent record than the pages

of my case-book are calculated to afford them, independent of the practical hint they convey.

It was on the 4th of August I was consulted by a respectable chain-cable manufacturer, who I found had been suffering from the first of the month from incessant hiccup. He was a thin, delicate man, of a sanguine temperament, and I found had sustained a severe pecuniary loss on the 1st of August, when, to use his own language, he felt a choking as if a ball was rising in his throat, and shortly afterwards the hiccup commenced, and which only ceased when from sheer exhaustion he dropped asleep, to be awoke shortly by a renewal of the hiccup. The complaint had continued now for the greater part of four days, without any amendment. It is unnecessary to detail the treatment, which proved wholly unavailing; suffice it to say, he took largely of the carbonate of magnesia, and also of valerian, camphor, and assafœtida. Opiates were also used without the slightest benefit, and the case went on until the 8th of August, on which day he remained in the same state, but his wife also had begun to hiccup, accompanied with globus hystericus, and on the day following his sister had also commenced, and the succeeding day, that is on the 10th, the maid-servant had got into the same state: it was a painful spectacle, although somewhat a ludicrous one, to see four individuals all at the same time hiccuping. It is the most extraordinary instance of imitative hysteria I ever witnessed, but what was worse, the remedies I have above enumerated had no effect in controlling the disease. However, on the 11th, something which the maid-servant took made her vomit, and from that moment the complaint ceased. I immediately ordered each of the others a mustard emetic, and was rejoiced to find that the sister also was cured after free vomiting: the wife did not so soon get rid of her attack, which, however, ceased for some time after the operation of the emetic, and she was now able to take her food, and a repetition of the emetic at the end of a few hours, and a warm stomachic with some of the carb. magnes., removed her complaint. Not so the husband, whose attack, however, was always suspended by vomiting, but soon returned. Now, however, he slept for considerably

longer periods, and the complaint was suspended while he was eating: he was put upon a similar plan as his wife, only the emetic was used every evening. Under this treatment he got gradually well, but it was full three weeks before he was entirely rid of the hiccup.

I do not recollect having seen any similar instances recorded, although no doubt similar instances have occurred; it had the effect, however, of giving me a lesson in the treatment of hysteria, which I have never had cause to regret, having always found vomiting put a period to the attacks, and the moral effect upon the patient is equally satisfactory, as I believe the dread of an emetic has often had the effect of a check to a hysterical attack.

I am, sir,

Your obedient servant,

EDWARD GREENHOW, M.D.

North Shields, Dec. 9, 1843.

CONTRIBUTIONS TO ANATOMY AND PHYSIOLOGY.

BY ROBERT KNOX, M.D. F.R.S.E.

Lecturer on Anatomy and Physiology, and Corresponding Member of the French Academy of Medicine.

The Corpus Luteum.

THE following very imperfect researches and inquiries were made shortly after the publication of my first memoir on the corpus luteum, four or five years ago. The more immediate cause of the delay in their publication was this. I had read, when first published, the work known by the name of "Sir Everard Home's Lectures on Comparative Anatomy," and at the period of my composing my first memoir on the corpus luteum I re-read the lecture having a reference to the subject of my memoir with every possible care, and with the deepest attention, being then aware that it contained, in all probability, the views of the "great master" himself, mingled up, no doubt, with much, both good and bad, from the pen of Sir Everard himself. My object was, if possible, to get at the *real opinions* of Hunter, as distinct from Home's theories and conjectures: this I fully anticipated being able to effect, because if it should turn out that Home's essay or lecture failed to furnish me with them, I might, during the

summer, inspect the Hunterian preparations themselves, and thus get a clue to the "theory" of the first of physiologists. In these expectations, however, I freely confess I have been disappointed; for, after having made, as I thought, a fair and impartial analysis of Sir E. Home's Lecture, my brother objected to the analysis, and offered me one of his own. That any thing was ever written in so inextricably confused a manner as this same lecture by Sir E. Home, I do most solemnly disbelieve; it exceeds in confusion anything I ever met with; nor am I at all singular in this opinion, for I have heard the same expressed by all anatomists I have conversed with. For this I account (if it be requisite to do so) by the peculiar circumstances under which the lecture was written; composed of the plunder of Mr. Hunter's manuscripts, which, without being understood, were then destroyed—of Mr. Clift's recollections; of an occasional glance at the preparations in the museum; of personal recollections of Mr. Hunter's conversations with himself; of a few very peculiar cases occurring in his own practice—out of these heterogeneous and, no doubt, discordant materials, did Sir Everard, adding thereto his own conjectures, concoct the "lecture" which has puzzled so many readers: and, during the concoction, keeping steadily in view his great object (a view persisted in by his followers in the Museum) of suffering to fall into abeyance, inasmuch as he could, the name of Hunter, by the substitution of his own.

Failing thus in making a satisfactory analysis of the "lecture," I next bethought me of Mr. Hunter's museum, in which I hoped to find these preparations so ticketed and marked as to enable me to guess at least with some show of probability at his real opinions. In this, however, I also failed, but from no want of courtesy or polite attention from those in charge of this altogether invaluable collection. I visited Mr. Hunter's museum in the summer season (June or July) of 1840, and examined the "division," having a reference to the "corpus luteum:" a MS. catalogue was kindly sent me by the conservators, but it had no reference to the preparations on the shelves; these had been originally put up, no doubt, expressly to corroborate Mr. H.'s views; but how were we to know

to what they referred? Fifteen preparations examined in succession were wrongly marked in the MS. catalogue, and their value destroyed by their history being unknown.

In this dilemma I naturally waited for the coming out of the printed volume of "the catalogue," which I was assured would very shortly appear: it did so, and I have examined it with some care: to me, it does not seem to contain the whole of Mr. Hunter's views on generation, and scarcely any of those on the natural history of the corpus luteum.

Having now explained the delay which has taken place since the publication of my first memoir, I now beg leave to submit to the public the following observations in continuation of my first inquiries. The concluding part must be delayed until next summer.

Whilst occupied with these inquiries, the ovaria of a cow were sent me which the butcher assured me never had had a calf, but the statement rests upon his authority, and not mine, and therefore I do not wish the reader to consider it as an undoubted fact; but be this as it may, in one of these ovaria there is a large and most distinct corpus luteum, quite similar to those found in the ovaria when a calf is present in the uterus. In the other ovary there is a second, somewhat smaller, and a third still smaller. Numerous vesicles of De Graaf are present and distinct.

It is not uncommon to find a miniature corpus luteum slightly adhering to the outer surface of a Graafian vesicle, but having no other connexion with it excepting with the capsules.

The bodies called false corpora lutea have, in the cow, precisely the same structure as the larger or true ones. I have satisfied myself of this fact repeatedly. In the ovaria, for example, of a cow in whose uterus was a calf of the size of a well-grown dog of about two months old, besides a large corpus luteum found in one ovary, a smaller existed in the opposite ovary differing in nothing from the first but in size.

We have only to examine a few ovaria in the sheep to be satisfied that there is nothing so inconstant as the mode in which the corpus luteum disappears after gestation and delivery,

occasionally continuing tolerably distinct for several months, whilst in other cases the same lapse of time causes its total disappearance. There is now before me the ovarium of a sheep, being precisely the contrast of the one alluded to above. This animal had a lamb in spring, and when slaughtered in autumn I find a still tolerably distinct corpus luteum, and with something even of an appearance of a central cavity.

Lastly, we do meet with the ovary of the cow in which neither true nor false corpora lutea appear.

I can ascribe the simplicity of Dr. W. Hunter's views respecting the nature of the corpus luteum, as compared to those of his brother, solely to his not having studied comparative anatomy so deeply, and to his having, therefore, viewed the question merely as an accoucheur. One or two references to Dr. W. Hunter's work on the gravid uterus will, I imagine, satisfy the reader as to this point.

In one of the engravings there is a view of the corpus luteum of a woman who died of flooding at the full period of pregnancy. In describing this drawing, and unquestionably the preparation from which it was taken, Dr. Hunter merely observes: "Here, in the substance of the ovary, the corpus luteum is seen split through the middle; no vessels appear at the centre, which is of a white complexion, but all around that centre its substance is very vascular."

In another plate the ovarium of a woman who died in the fifth month of gestation is represented. Now, on examining these two figures, there are clearly the remains of other corpora lutea, or, as I should rather say, miniature ones, of which Dr. Hunter has taken not the slightest notice. He seems never to have entertained the slightest doubts as to the history of what he calls "*the corpus luteum*," which he seems to have regarded as the product of conception. I am not, at the present moment, prepared to say what were his notions respecting these bodies we now call false corpora lutea; but his language, which I have quoted in describing the figures, clearly convinces me that he paid little attention to their presence. It seems to have been reserved for his brother (John Hunter) to bring again before the public

those difficult questions which did not, however, originate with him, but had been, often discussed before by Santorini, Morgagni, and the observers of that epoch.

I have experienced very great difficulty in getting at what may be considered John Hunter's opinions respecting the structure and nature of the corpus luteum. I am not aware, for example, of his having published any separate memoir on the subject. His manuscripts were burned by his son-in-law, Sir E. Home, and the curators of his museum have hitherto refused to publish a *plain and simple account of the Hunterian preparations as they stood at the time of his death*. Had they presented to the public a brief and simple outline of those preparations of the ovaria which Mr. Hunter put into his museum with his own hands, I have little doubt that we should then have been able to have guessed pretty nearly at Mr. Hunter's views, but in the absence of such, there remains another mode of forming at least a conjecture as to Mr. Hunter's theories respecting the corpus luteum, viz. by examining the lecture on generation published by Sir E. Home in his *Lectures on Comparative Anatomy* (Vol. 3), and which Sir E. Home admits in his preface, and in his evidence before the Commissioners of Enquiry, to have been made up chiefly of extracts from the manuscripts he had destroyed, in addition to which evidence, if it required any confirmation, we have, if I mistake not, the further testimony of Mr. Clift, who assisted in copying these manuscripts, and preparing them for the press, under Sir E. Home's name.

I now proceed, therefore, to examine the substance of Sir Everard's lecture on generation. This I find the most difficult task I ever experienced, for anxious to conceal the fraud he was practising upon the public, he has mixed up almost in every page some crude notion of his own, rendering it nearly impossible to speak positively as to what Mr. Hunter's views really were.

I shall pass over, for the present, Sir Everard's story of the discovery of a very early ovum, examined by him along with Mr. Clift, and drawn by Baer, which has excited so much ridicule throughout Europe.

Mr. Hunter apparently believed the

corpus luteum to be a glandular structure, which forms the ovum or ovule, and when the ovum is expelled, gradually disappears, whether the ovum be the product of conception or not. He seemingly entertained the idea, that the formation of the corpus luteum containing the ovum was the cause, and not the effect, of impregnation, *i. e.* that the corpus luteum is first formed, that it next generates the ovum, and that then, and then only, impregnation may take place by the accidental presence of the male; but should this not happen, the ovum, or rather ovule, is discharged, but of course does not come to maturity. Mr. Hunter seems to have thought, moreover, that the source of the error into which medical men had fallen in respect to this important fact in physiology, lay in the circumstance of there being almost always in the ovarium of a woman dying in child-bed a corpus luteum preparing another ovum to be ready for future impregnation, and that this corpus luteum is usually mistaken for that belonging to the child in utero, or just born, whereas the former corpus luteum, that really belonging to the child then born, had entirely disappeared.

It is extremely probable that the latter part of this theory will prove untenable, but this does not disprove the first part, *viz.* that the corpus luteum begins first to form previous to all impregnation; that to discharge the ovule or ovum from the ovarium the preexistence or coexistence of a corpus luteum is essential, and that this may happen as well in the virgin as in the married woman, thus giving rise to these *miniature corpora lutea*, as I have ventured to call them, instead of *false*, since they are just as much true as that larger one always existing contemporaneously with a fœtus in the uterus. Indeed, the only difference I have been able to observe between a corpus luteum which has given origin, or at least discharged from the ovarium a fertile ovum, and that which has formed independently of impregnation, is the *comparative size*; the latter being, in the human female, perhaps always small, and often but imperfectly formed, the former being as uniformly fully developed.

But to return to what I must consider, for the reasons assigned above, as having been one of the views held by

Mr. Hunter. I next endeavoured to make out from Sir E. Home's memoir (which, with the sanction of Mr. Clift, he calls "A Descriptive Catalogue of the Hunterian Preparations,") what preparations Mr. Hunter had actually left in his museum at his lamented death, illustrative of his views on "generation." But this I found an extremely difficult task, from the advisedly confused style in which they have been mentioned by Sir Everard. They seem to me to have been as follows; but if in error, it will surely be an easy matter for any member of the London College to give a plain, simple, and intelligible description of "the preparations left by Mr. Hunter at his death illustrative of his peculiar views in respect to the corpus luteum."

1st. The ovarium of a woman 70 years of age: she had given birth to twelve children, and there exist distinct remains of numerous corpora lutea*.

2d. Specimens of the external organs of the human female, with the hymen entire, and in whom the ovaria shewed corpora lutea.

3d. There exist in Sir E. Home's paper some confused hints that Mr. Hunter verified the fact experimentally on the lower animals by locking up the female pig, and thus proving that corpora lutea might originate and become fully developed in the virgin animal; and it is also hinted that the preparations to prove this were deposited by Mr. Hunter in his museum. Were this fully and satisfactorily made out (which, however, is very far from being the case) then the question as to the nature of the corpora lutea is decided in the lower animals, but even then the analogy could scarcely be extended in all its latitude to the human female.

Since the publication of Mr. Hunter's descriptive catalogue by Sir E. Home, two very valuable contributions to this department of physiology have been given to the public by Dr. Montgomery and Dr. Lee. The points in which I venture to differ from these gentlemen have been already partly stated; I shall only, therefore, add, that I am fully

* Contradictive in terms to the previous remarks of Mr. Hunter, *viz.* that the corpus luteum entirely disappears in a few months after conception, or, at all events, delivery.

satisfied that the distinctive definition of a true and false corpus luteum in the human female by Dr. Montgomery will never hold its ground, and that as yet the results of the inquiry could not be employed safely by the medical jurist. The appearance of a cicatrix in the corpus luteum of a certain age, which Dr. Montgomery thinks the test of a true one, is, most assuredly, frequently wanting in specimens which are of unquestionable authenticity; nor is the cavity always present in the early corpus luteum. Thus, whilst it may be admitted, with Haller, that "conception never happens without the production (coexistence?) of a corpus luteum," the accuracy of the following opinion, which I quote on the authority of Dr. Montgomery, and which also belongs to Haller, may still be doubted—"the corpus luteum is never found in virgin animals, but is the effect of impregnation."

From these details I shall venture to draw the following conclusions:—There is no distinctive character by which the corpus luteum (true) can be distinguished from the miniature corpus luteum (false).

That the full-sized corpus luteum, always found coexisting with a fetus *in utero*, seems to be the one from which the embryo of that fetus came, and not that preparing a future embryo, as Mr. Hunter seems to have thought.

That there are no good grounds for supposing that corpora lutea do not form in virgin animals, and even in woman. But in the virgin human female they never seem to attain to any size, but remain diminutive.

That the question of the discharge of ova from the ovary by virgin animals is quite open for investigation. In no single species has the history of this phenomenon been made out. Thus, in some, as in the human female, the escape of the unimpregnated ovule from the ovary may be capricious, irregular, or never even take place, whilst in the lower animals it may be periodical; but in one point it is highly probable that they all agree—that no ovule escapes from the ovary impregnated, or not without the coexistence of a peculiar structure known by the name of corpus luteum.

That in respect to the central cavity of the corpus luteum, this may or may not be present, though observed pre-

cisely at the same period in different women. The same may be said of the central fold, which is often wanting in an undoubted corpus luteum.

The total disappearance of the corpus luteum presents the utmost variety, having a range, as I myself have observed, of from three months after delivery at full term, to an almost indefinite period.

Upon the whole, then, it would appear, with reference to the great question of virgin corpora lutea, that such bodies form altogether independently of impregnation, most assuredly in the lower animals, and in all probability even in woman, but that such corpora lutea never do attain the size of that one which coexists with, or follows, impregnation.

PUSTULAR OPHTHALMIA.

To the Editor of the Medical Gazette.

SIR,

IT is six years since I requested, in consultation, a medical practitioner of this island to try the grey powder for pustular ophthalmia, as I found it, combined with bark, to remove the disease with scarcely any local treatment; since which time he and others have reported favourably of the remedy. They had neither used it, nor heard of its being used, with the same intention. I hope, in troubling you with these few lines, to hear, through the medium of your publication, a favourable report of what I have found to be a most useful remedy in a very obstinate disease; and if any person have previously published it, I am happy to corroborate its utility.

By referring to my paper on oiled silk, in the *MEDICAL GAZETTE* of March 1841, you will find the above treatment recommended in serofula; and also the green French oiled silk is substituted for the pasteboard shade in general use in ophthalmia. The only local treatment is a little extract of belladonna, with spermaceti ointment, applied to the lids, as I consider that eye-water or drops retard the cure. I sometimes begin with blood-letting (no leeches) where the pustule requires quicker action and when temporary relief from the intolerance of light is of importance, I direct a blister to the back of the

neck; but the chief reliance is to be placed in hydrarg. c. cretâ, its action quickened by quinine, and corrected by Dover's powder.

The first case in which I found the beneficial effect of the powder was a young lady about 17 years of age, of strumous constitution. She was on a visit in France, and the doctor who attended her having tried the usual remedies without improvement, became alarmed for her sight, and sent her home; in fact, when I saw her she was almost blind.

The second case was a little girl 4 years old, who came from England, having already undergone medical treatment. She was placed under the care of the oldest practitioner in this island, who, after some time, called in a celebrated French oculist; and from the state she was in when I saw her, I concluded that the ordinary treatment had failed.

The third case was the son of a general practitioner, 7 years old; had been a long time subject to a pustule on the cornea, and, from the great difficulty in making him take medicine, he had the hydrarg. c. cretâ only in the form of lozenges.

The following after-treatment, to prevent relapse, is often indicated: iodine and sarsaparilla, chalybeates, or quinine.—I am, sir,

Your obedient servant,

ALEX. LEIGH, A.B. M.B.

Late Royal Rifles.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

HOW TO KEEP ONESELF WARM.

THERE are two classes of persons, said Boerhaave, who suffer from cold—beggars and fools; the former not being able to procure a sufficiency of clothing, the latter not having sense enough to wear it.

Sir George Lefevre, in a pamphlet

called "Thermal Comfort," has endeavoured to diminish the number of the latter class, and to show that life may be prolonged by warmer clothing and warmer rooms than it is customary to use in this country.

Dr. Thomas Young has observed, that the duration of a case of phthisis varies from six weeks to forty years; and Sir George attributes the prolongation of cases to twoscore years simply to warmth.

The consumptive, even when lying in bed, can detect variations in the temperature of their rooms, which are imperceptible to the healthy. Hence the great advantage which they derive from a residence in the equable climate of Madeira; and hence, too, the benefit which they experience when confined to rooms of unvarying temperature, without quitting their native country.

It is proved by the Bills of Mortality, that consumption carries off one-fifth of the population of the British Isles; and as the deaths from this disease are much fewer in more northern latitudes, Sir George ascribes the difference to the warmer clothing adopted in those icy regions. We should attribute it, in part, to the greater variableness of English weather. Moreover, a strong objection might be made to Sir George's deduction from the fact. As the whole mortality of northern climates is greater than in England, it would appear that the gain in phthisis is more than made up by the loss in other diseases; and it might be urged, that if stoves save the lungs, they attack the brain or the bowels, or whatever other channels the mortality of Russia selects. However, we will not be too syllogistical; we will take good where we find it, and will candidly confess that many of Sir George's suggestions would add to comfort, and some, probably, to health also.

It is a vulgar error, as he observes,

to suppose that the Laplander does not feel cold, or becomes accustomed to it. We recollect that Mr. Catlin refuted the same mistake touching the North American Indians. The truth is, that in climates where the thermometer at zero of Fahrenheit is a mere indication of seasonable weather, substantial clothing is the first necessary of life. There is no dallying with a cold that freezes brandy. Your Laplander or Kamschatkan braves the frost—in a suit of furs.

The Draconic law of nature in those countries says, “Wear furs, or die!” “Keep your cottage warm, or die!” The Russian peasant submits to the condition:—

“His door shuts close; his window-frames are double, two feet by three, the glass, or oiled paper, fixed in. In the corner of his room is a stove, whose chimney finds exit through the roof; no wide open place to allow of heat to ascend, and cause a continual draft of air. His hut is insupportable to those who are unaccustomed to such in-door temperature. The flies, congregated in some corner, hang down like a swarm of bees, happy and buzzing in the *winter season*. He himself lies prostrate on his stove, which serves him for a bedstead. This man is a rare subject for consumption.”

The man in easy circumstances does the same thing, with a difference. If you go into his rooms, and observe upon its warmth, he answers with a Russian proverb, that heat breaks no bones. It would be a woeful offence to enter his parlour with your great coat on. In fact, it would be like insulting a jovial host by bringing a bottle of wine as your contribution to his table. The Russian shows his hospitality by his generous contribution of caloric, *liqua super foco largè reponens*, though he probably does not forget, at the proper moment, *deponere quadrivium merum diotâ*. The English resident in Petersburg adopts the same precautions.

“Double doors protect the ante-room from the cold air of the staircase.* Upon entering, a sensation of hot-house heat is experienced, for this room is kept warmer than the other chambers. Once in the interior of the house, no perceptible difference is to be found in any of the rooms. Caloric has diffused itself equably through all of them. Whether it be in the dining, or in the drawing-room, or in the bed-chamber, or in the staircase by which you reach it, (when not upon the same flat) you move in the same equable temperature. Double windows, fitted close into immensely thick walls, exclude the external air. The rooms are warmed by stoves,” &c.

It might be difficult to gauge the precise wholesomeness of a hot-house temperature in one's dwelling; but it is easy to see that it must be eminently delightful, for a time, at least. Very pleasant did we find the German stove in our bed-room at Cologne, some six weeks ago. Nor did November allow us to find the smallest fault with the down bed above as well as below us, which has been the object of so much satire; in short, we were perfectly contented with what has been called “a spare bed on the Rhine.”

Sir George Lefevre gives an amusing letter from an Englishman (himself?) spending a winter in his own country, to his friends in Russia, where he had lived for ten years. He finds that he does not want his furs, but complains grievously of the indoor cold. No stove in the ante-room! No double windows! The water is frozen in the jug in his bed-room, and he amuses himself in bed by trying to recognize the species of plants drawn by Jack Frost upon the window-glass. Every gust of wind makes the casements rattle; draughts come from the windows, draughts come from the door, and make the carpet dance up and down, if not fastened by

* How can the air of the staircase be cold? It is said, at the end of the quotation, to be of the same temperature as the dining-room, &c.; indeed, in the next page, we are told that the staircases are heated by stoves.

nails; and the unhappy Anglo-Russ even asserts that "if the rain pelts against the windows, it penetrates through the sashes, and runs down upon the window-seat." He bemoans his hard fate, and fears that poor Amelia, whose cough is getting worse, will fairly sink under these accumulated ills.

The letter is a clever drawing after nature. Yet, windows that admit the rain, and dancing carpets, are rarely to be found except in the houses of the negligent; but stoves and double windows are scarce everywhere, and frozen jugs very common.

The reason is plain enough. Although a fire is a pleasant thing in England for eight months in the year, intense cold is seldom or never of long duration. Hence it is thought unnecessary to use stoves, or keep up a hot-house temperature in our dwellings. The makers of thermometers tell us on their scales what heat is necessary for melons and pine-apples, but they have forgotten to inform us which is the best temperature for complexions. We rather conjecture, however, from what Sir George says, that rosy cheeks are more common in England than in Russia. The consumptive may prolong their lives by a stove-heated range of apartments; but ordinary lungs, well protected by blankets, will not be injured by the air of a bed-room at 40°, though Jack Frost should paint whole galleries on the panes.

We must loudly protest, too, against Sir George's recommendation of nailing down windows to prevent their rattling in the chamber of an invalid. We should prefer the insertion of a piece of wood between the sash and the frame, which can be taken out when the window is to be opened. Neither Russia nor England is perfect in these points. "'Your rooms have a close, musty, sickly smell,' says the English

traveller in St. Petersburg. 'On est toujours dans un air coulant,' said a lady to me who had passed two years in London and Edinburgh."

Our Anglo-Russian physician, however, thinks that a *juste milieu* might be hit upon. He offers to give up stoves, on condition that we abolish rattling casements, draughts under the doors, and dancing carpets. Done.

Moreover, "in cold weather, fires should be kept up day and night." Most willingly; if Sir George will give us an easy fortune, or make coals cheap in the metropolitan district. In many parts of England this recommendation is acted on. In Wolverhampton, for instance, where the best coals are about six shillings a ton, it would be foolish to let the fire go out.

And now one word about clothes. The same cause which has prevented the adoption of stoves, namely, the general mildness of our winters, has, with less reason, induced a multitude of persons to dress with too little regard to the long-extended chilliness, and occasional coldness, of our weather. Every year we have ten or a dozen days, when a suit of furs would be agreeable, but few can afford an expensive vestment to be used so seldom. Granted; but our gymnosophists go much farther than this; for as they find that the cold is rarely intense, they confound the possible with the expedient, and brave the frosts of January in their autumnal garments. Indeed, it seems to be considered a mark of manhood to use a minimum of wool; and not only the young man of five-and-twenty, but the grave professor, at a much later epoch, may be seen indulging in this unnecessary martyrdom.

Sir George recommends outer coverings, in their several gradations, to suit the varieties of weather, from the picturesque Taglioni to the sober great-coat; and a large silk handkerchief to

tie round the neck at night; for he says that in this essay he chiefly advocates "the Hibernian method of treating complaints, viz. the preventive one."

But this must be enough for the present *de re vestiaria*.*

ELECTION AT ST. GEORGE'S HOSPITAL.

THE election of an assistant-surgeon, to which we alluded in our number for December 1, terminated on the 15th, in the defeat of the medical officers and the candidate whom they supported. This result is an event of some moment, as it breaks the chain of success (we believe invariable) which has hitherto attended their protégé. The numbers were—

For Mr. Johnson . . .	169
For Mr. Hawkins . . .	152

Giving a majority of . . . 17

The circumstances were altogether rather peculiar, and appear to have placed the hospital staff on the horns of a dilemma. Mr. Tatum, and Mr. Henry James Johnson, the two gentlemen last elected, were both teachers in Kinnerton Street; and to have supported a third candidate from the same quarter, would have had the appearance of intending to make the lectureship in the anatomical school alluded to a passport to the hospital, which certainly was to be avoided. But this would have been equally accomplished by their remaining neuter, which the result has shewn would have been their most eligible course. Had they supported Mr. Johnson, it is extremely probable that considerable jealousy would have been excited; but no sooner did they declare against him than a reaction took place; and we are not sure

that he did not, in this indirect way, rather gain than lose by their opposition.

Mr. Johnson, who had very high testimonials from Sir Benjamin Brodie and Dr. Chambers, is unquestionably perfectly qualified to fill the office to which he has been elected; and to satisfy all parties, we believe, it only remains that he assiduously exert himself in the discharge of his important duties.

WESTMINSTER HOSPITAL.

On Tue-day the 12th, B. Phillips, Esq. was elected assistant-surgeon to the Westminster Hospital.

RELIEF OF THE POOR.

To the Editor of the Medical Gazette.

SIR,

LORD ASHLEY has written to remind me of his intention to bring the subject of medical relief to the poor before Parliament at the commencement of the ensuing session, and I beg your permission to remind the members of the medical profession, through your journal, that his success in obtaining a committee must depend upon the number and accuracy of the facts he may be able to bring forward in proof of the necessity for a full and fair inquiry into the subject. I am greatly obliged to those gentlemen who have been so good as to communicate with me during the last twelve months, and will beg of them to write between the 10th and 20th of January, if any change should have taken place in the facts and circumstances they then made me acquainted with.

I need hardly repeat to the members of the profession, that this will be in all probability the last opportunity they will have of redressing their own grievances, and those of the unfortunate poor committed to their charge.

I shall be happy to present any of those who are particularly interested in this subject to Lord Ashley, and to give them every opportunity of explaining to him their own views. He has no predilections, and is only desirous of doing that which it may be

* Sir George Lefevre asserts that it was one of the "quaint sayings" of Sydenham, that in the treatment of phthisis his physician was a horse and his apothecary an ass. Not so: the man belongs to Guy Patin. See MEDICAL GAZETTE, April 21, 1838, p. 152.

just and right to do for the poor, and for their medical attendants.

It is exceedingly desirable that all who have influence with members of Parliament, should lose no time in interesting them to the utmost of their ability in supporting and promoting Lord Ashley's inquiry.—I am, sir,

Your obedient servant,

G. J. GUTHRIE.

4, Berkeley Street,

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

December 12, 1843.

THE PRESIDENT IN THE CHAIR.

Case of alarming Syncope from the Admission of Air into a Vein during an Amputation at the Shoulder-joint. By BRANSBY B. COOPER, Esq. F.R.S. Surgeon to Guy's Hospital.

THE patient, a female, nineteen years of age, was admitted on the 17th of May, 1843, under the care of the author, for enlargement of the middle third of the humerus. She had suffered pain in the seat of the disease for eight months, but the swelling did not commence till six weeks before her admission into the hospital. From the history and the examination of the arm, the tumor was considered to be a malignant disease of the bone, and amputation at the shoulder-joint was resolved upon. This operation was performed on the 23d of May. The arm was removed in less than a minute, and with very little loss of blood. When the limb had been severed from the body, the patient, who had borne the operation with great fortitude, expressed her thankfulness in a firm and audible voice. The subclavian artery was immediately secured, but its compression still retained upon the first rib, as there were small vessels requiring ligature. The author then proceeded to remove a gland, which was somewhat enlarged, from the axilla; and while dissecting it from its cellular attachments, he distinctly heard a peculiar gurgling noise, like air escaping with fluid from a narrow-necked bottle; and at the same instant the patient fell into a state of collapse, threatening immediate dissolution: the countenance was deadly pale; pupils fixed, and unobedient to light; the pulse quick, small, and fluttering, although at intervals regular; the respiration was irregular, being hurried and feeble, and attended occasionally with a deep sigh. The patient was directly placed in the horizontal posture, the flap brought over the wound, and retained by plaster; and various stimulants were administered. An hour elapsed before she was sufficiently recovered to be removed from

the operating theatre. Upon being placed in bed, she passed her fæces and urine involuntarily. When the reaction was coming on, she uttered a continued whining cry, and maintained a constant motion of alternate flexion and extension of the right leg, while the left remained perfectly quiescent, and seemed insensible to feeling, as well as motionless. She complained also of pain running up the right side of the head and neck. For several days she remained with her eyes closed. The lower extremities in the same condition as described, and the pulse very frequent. It was found necessary to give her opiates at different times, which relieved her general restlessness, and procured sleep. On the fourth day, the left leg was also affected with involuntary contractions; but these subsided on the following day. On the 25th day she was able to leave her bed. The motions of the right leg had ceased at this time, but she complained of great numbness and loss of power in the left leg. On the 3d of July she was sufficiently recovered to leave the hospital, having no other unfavourable symptom but a slight dragging of the left leg. The author concluded his paper by adding remarks on the consequences of air being admitted into the veins, and pointed out the resemblance between the symptoms in his case and those presented in other similar cases upon record, as well as in experiments upon the lower animals, made to elucidate the subject. He drew attention to the different effect produced in man compared with brutes by the admission of air, owing to the influence of mental agitation on the motions of the heart in the former. He also dwelt on the various modes of death in such cases, according as the air introduced distended and paralysed the walls of the right cavities of the heart, or was sent onwards, mixed with the blood, to the lungs, or was transmitted by the arteries to the brain; and he ended by offering some practical remarks on the best mode of guarding patients from such dangerous occurrences in operations about the neck and shoulder.

The next meeting of the Society will be held on Tuesday, the 9th of January, 1844.

CHRONOLOGICAL SCHEDULE OF THE FELLOWS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

WE subjoin a list of the Fellows of the College of Surgeons, which has just appeared:—
John Goldwyer Andrews, St. Helen's Place.
Sir Benjamin Collins Brodie, Bt. Saville Row.
Samuel Cooper, Woburn Place, Russell Sq.
Honoratus Leigh Thomas, Leicester Place.
Robert Keate, Albermarle Street.
John Painter Vincent, Lincoln's-inn-Fields.

- George James Guthrie, Berkeley Street.
 Anthony White, Parliament Street.
 Thomas Copeland, Cavendish Square.
 James Briggs, Edgware Road.
 William Lawrence, Whitehall Place.
 Benjamin Travers, Bruton Street,
 Joseph Swan, Tavistock Square.
 Edward Stanley, Brook St. Grosvenor Sq.
 Joseph Henry Green, Hadley, Middlesex.
 Thomas Callaway, Wellington St. Southwark.
 George Gisborne Babington, Golden Sq.
 Robert Liston, Clifford Street.
 James Moncrieff Arnott, New Burlington St.
 John Flint South, Blackheath Park, Black-
 heath.
 John Morgan, Finsbury Square.
 Robert Rainy Pennington, Portman Square.
 Alexander Ogilvy, Montague Square.
 Richard H. H. Steel, Berkhamstead.
 Thomas Nixon, Pepperwick, Notts.
 James Borland, Teddington.
 Sir Simon Heward, Knt. Carlisle.
 John Gunning, Paris.
 William Hey, Sen. Leeds.
 Robert Bloxham, Isle of Wight.
 Richard Cartwright, Bloomsbury Square.
 Thomas Beckett, Russell Place.
 Stephen Woolrich, Bridgnorth.
 James Annesley, Albany.
 George Frederick Albert, Cheltenham.
 Henry Parkin, Marine Barracks, Woolwich.
 Thomas Kidd, A., Corfu.
 Joseph Constantine Carpué, Charlotte St.
 Fitzroy Square.
 Sir James Pitcairn, Knt. A., Cork.
 Henry Coates, Salisbury.
 Sir Stephen Love Hammick, Bt., Cavendish
 Square.
 George William Young, Mortimer Street.
 Joseph Langstaff, Cambridge Square.
 John Smith Soden, Bath.
 Charles Seager, Clifton.
 William Henchman Crowfoot, Beccles,
 Suffolk.
 William Percival, Sen., Northampton.
 George Norman, Bath.
 Samuel Dyer, Cambridge Ter., Hyde-Park.
 John Bacot, Portugal St., Grosvenor Sq.
 Richard Wood, Birmingham.
 John Harris, Exeter.
 John Badley, Dudley.
 Bowyer Vaux, Birmingham.
 Sir John Chapman, Knt., Windsor.
 William Attree, Brighton.
 George Gunning Campbell, Montague Sq.
 George Langstaff, New Basinghall Street.
 Samuel Ludlow, Exeter.
 Jonathan Toogood, Bridgewater.
 Sir Augustus West, Knt., Paris.
 Morgan Thomas, Woolwich.
 Thomas Davis, Brook St. Hanover Sq.
 William Andrews, Salisbury.
 James Dawson, Liverpool.
 John Ridout, Montague Street.
 John Augustus Knipe, United Service Club.
 Vero Clarke Kemball, Oriental Club.
 John Wright, Derby.
 Hugh Chudleigh Standert, Taunton.
 Charles Farrell, Dalyston, Loughrea.
 John Atkinson Ransome, Manchester.
 Robert Bickersteth, Liverpool.
 Charles Boutflower, Liverpool.
 Kenrick Watson, Stourport.
 John Bishop Estlin, Bristol.
 George Champney, York.
 James Ainsworth, Manchester.
 Andrew Brown, Paris.
 Richard Bennett Godwin, Derby.
 Harry Blaker, Brighton.
 William Tuckwell, Oxford.
 William Bewicke Lynn, Sloane Street.
 John Grenfeli Moyle, Charlton Kings, Chel-
 tenham.
 William Goodlad, Manchester.
 James Pook Sheppard, Worcester.
 John North, Gloucester Place.
 Robert Thorpe, Manchester.
 Charles Wingfield, Oxford.
 John Lawrence, Brighton.
 Thomas Martin, Reigate.
 Richard Willson Brown, Bath.
 Richard Blagden, Albemarle Street.
 Charles Mayo, Winchester.
 Gideon Algernon Mantell, Clapham Comm.
 Samuel Barnes, Exeter.
 William Cother, Gloucester.
 John Haddy James, Exeter.
 John Nedham, Leicester.
 Matthew Pierpoint, Worcester.
 William Rae, Melville Hospital, Chatham.
 Joseph Hodgson, Birmingham.
 Samuel Smith, Leeds.
 Henry Terry, Northampton.
 Alfred Jukes, Birmingham.
 John Clarke, Speddock, near Dumfries.
 John Cooper, Liverpool.
 William Lloyd Thomas, Hatfield.
 Charles Henry Phillips, Cleveland Row, St.
 James's.
 John Baird, Newcastle-upon-Tyne.
 Thomas Joseph Pettigrew, Saville Row.
 William Jackson, Sheffield.
 Robert Tayler, Brighton.
 John Green Crosse, Norwich.
 William James Wilson, Manchester.
 William Cleobury, Oxford.
 William Hunter, Surgeon-Major, Guards.
 John Okes, Cambridge.
 James Wardrop, Charles Street, St. James's.
 Montague Gosset, Broad Street Buildings.
 Thos. Michael Greenhow, Newcastle-on-Tyne.
 Sir John Fife, Knt, Newcastle-on-Tyne.
 James Ranald Martin, Grosvenor Street.
 William Wright, Nottingham.
 William Kingdon, New Bank Buildings.
 William Couborough Watt, Royal Naval
 Hospital, Malta.
 Robert Harrison, Dublin.
 James William Braine, Cleveland Row.
 George Beauchamp Knowles, Birmingham.

- Robert Armstrong, Plymouth Hospital.
 Thomas Turner, Manchester.
 John Bontflower, Manchester.
 Henry Giles Lyford, Winchester.
 William John Wickham, Winchester.
 John William Wilton, Gloucester.
 Joseph Prince Garlick, Leeds.
 John Mawdsley, Hanover Square.
 Edward Tegart, Bryanston Street.
 Sir John Webb, Knt. Woolwich.
 Sir Jacob Adolphus, Knt. Cheltenham.
 John Yarrow Arrowsmith, Shrewsbury.
 Eusebius Arthur Lloyd, Bedford Row.
 Daniel Henry Wahe, Guildford Street.
 Henry Edward Burd, Shrewsbury.
 Thomas Arthur Stone, Clifford Street.
 William Hey, jun., Leeds.
 Richard Hughes, Stafford.
 John Masfen, Stafford.
 William MacKenzie, Glasgow.
 Andrew White, Hertford Street, May Fair.
 George Macilwain, Argyll Place.
 Thomas Paget, Leicester.
 John Hopps, York.
 George Buckley Bolton, Pall Mall.
 Robert Craven, Hull.
 Robert Ceeley, Aylesbury.
 Herbert Mayo, Boppart.
 Philip Chilwell De la Garde, Exeter.
 Francis Peter Ballard Samwell, Margaret Street, Cavendish Square.
 George Sampson, Chester Street.
 Robert Wade, Dean Street, Soho.
 John Prince Halton, Liverpool.
 Richard Welbank, Chancery Lane.
 John Scott, New Broad Street.
 Edward Cutler, New Burlington Street.
 William MacKenzie, Edinburgh.
 Isaac Hurst, Bedford.
 Charles Aston Key, St. Helen's Place.
 John Whitaker Johnson, Derby.
 Douglas Fox, Derby.
 James Syme, Edinburgh.
 Richard Thomas Gore, Bath.
 Cesar Henry Hawkins, Half-Moon Street.
 Richard Duguid Grainger, Annerley, Norwd.
 Fred. J. R. Hale Thomson, Berners Street.
 James Luke, Broad Street Buildings.
 John Maurice Banner, Liverpool.
 Thomas Pridgin Teale, Leeds.
 William Eccles, Old Broad Street.
 Benjamin Henry Norgate, Norwich.
 William Francis Morgan, Bristol.
 Frederick Huntington, Hull.
 Price Blackwood Hallowses, Canterbury.
 David Browning Major, Canterbury.
 John Colley Taunton, Hatton Garden.
 Rich. Anthony Stafford, Old Burlington St.
 Bransby Blake Cooper, New St. Spring Gard.
 William Sands Cox, Birmingham.
 Thomas Wormald, Bedford Row.
 George Pilcher, Great George St. Westm.
 John Bishop, Bernard Street.
 John Geo. Perry, Gt. James St. Bedford Row.
 George Simpson, Bedford St. Bedford Sq.
- Gilbert Wakefield Mackmurdo, N. Broad St.
 Francis Kiernan, Beaumont St. Marylebone.
 Henry Heath, Newcastle-on-Tyne.
 Henry Russell, York.
 John Harrison, Bristol.
 Thomas Green, Bristol.
 Richard Hey, York.
 John Malyn, James's Street, Westminster.
 George Gulliver, Royal Horse Guards, Blue.
 Edw. Wm. Tuson, Russell Place, Fitzroy Sq.
 Henry Clarke, Bristol.
 Richard Owen, College of Surgeons.
 John Willimott.
 Wm. Coulson, Frederick Place, Old Jewry.
 Joseph Jordan, Manchester.
 Wilson Overend, Sheffield.
 John Dalrymple, Grosvenor Street.
 Samuel Gregory, Sheffield.
 Richard Middlemore, Birmingham.
 Richard Partridge, New St., Spring Gardens.
 John Hilton, St. Thomas's Street, East.
 William Henry Bainbridge, Liverpool.
 Richard Quain, Keppel Street, Russell Sq.
 George Mills White, Nottingham.
 Thomas Cox Buchanan, Gloucester.
 Henry Thomas Chapman, Lower Seymour St.
 Edward Cock, St. Thomas's St. Southwark.
 Henry Denne, Canterbury.
 Sam. Wm. Langston Parker, Birmingham.
 Samuel Solly, St. Helen's Place.
 Thomas Tatum, George St. Hanover Sq.
 Alexander Shaw, Henrietta St., Cavendish Sq.
 John Adams, New Broad Street.
 Alfred Hamilton, Broad Street Buildings.
 George T. Morgan, Cleveland St. Fitzroy Sq.
 Henry Douglas Carden, Worcester.
 Samuel Armstrong Lane, Grosvenor Place.
 John Avery, Saville Row.
 Frederick Dover, Great Coram St. Russell Square.
 John Hobbs, Southampton Row.
 James Farish, Lancaster Place, Strand.
 John Dickin, Shrewsbury.
 William Pemington, Montague Place.
 Henry Clinton Attenburrow, Nottingham.
 Dickenson Webster Crompton, Birmingham.
 Andrew Melville McWhinnie, Crescent, New Bridge Street.
 Edward Wallis, Hull.
 Alfred Joshua Wood, Gloucester.
 Benjamin Phillips, Wimpole Street.
 Henry Cooper, Hull.
 George Roberts Tatum, Salisbury.
 Charles Beevor, Berners Street.
 Henry Jackson, Sheffield.
 George Busk, Dreadnought Hospital Ship.
 Thomas Wilkinson King, Bedford Square.
 John Godwin Johnson, Norwich.
 Henry Thomas, Sheffield.
 Henry Stubbs, Liverpool.
 Charles Lestouurgeon, Cambridge.
 William Gill, Liverpool.
 Rutherford Alcock, Bolton Street.
 Benj. Travers, jun., St. Thomas's Hospital.
 Nathaniel Smith, Bristol.

Wm. James Erasmus Wilson, Upper Charlotte St. Fitzroy Sq.
 Thomas Nunneley, Leeds.
 Robert Hughes, Stafford.
 William Henry Fletcher, Gloucester.
 John Harrison, Charles Street, Berkeley Sq.
 James Long, Liverpool.
 Thomas Blizard Curling, New Broad Street.
 Frederick Le Gros Clark, Finsbury Square.
 Carsten Holthouse, Serle Street.
 John Farrar Crookes, Suffolk Pl. Pall Mall.
 Archibald Dalrymple, Norwich.
 Edward Francis Lonsdale, Guildford Street.
 Henry Charles Johnson, Saville Row.
 Henry James Johnson, Suffolk Place, Trafalgar Sq.
 Cornelius Harrison Browne, Canterbury.
 Chas. Hy. Rogers Harrison, Southampton St., Fitzroy Sq.
 Philip Bennett Lucas, Manchester Street.
 Dennis Embleton, Newcastle-on-Tyne.
 Henry Hancock, Harley Street.
 John Gay, Pavement, Finsbury.
 John Newton Tomkins, Russell Place, Fitzroy Sq.
 Samuel Holmden Amphlett, Birmingham.
 Charles Lewes Parker, Oxford.
 Alexander Ure, Charlotte St. Bedford Sq.
 George Lewis Cooper, Keppel Street.
 William Morrison, New Castle-on-Tyne.
 George Newport, Somers St. Oxford Terr.
 George Viner Ellis, George St. Hampstead Road.
 James Duncan, Edinburgh.
 Thomas Morton, Woburn Pl. Russell Sq.
 Ewd. John Chance, Newcastle St. Strand.
 Campbell Grieg De Morgan, Manchester St.
 John Chippendale, Great Queen Street.
 James Dixon, Broad Street Buildings.
 James Paget, St. Bartholomew's Hospital.
 Josiah Hammond, Cambridge.
 Prescott Gardner Hewett, Vigo Street.
 Francis Hird, Cleveland Row, St. James's.
 Richard William Tamplin, Great Queen St.
 Charles Hawkins, Court Yard, Albany.
 William Trew, Woburn Place, Russell Sq.
 Henry Smith, Henrietta St. Cavendish Sq.

CASE OF EPILEPSY, INDUCED BY A BLOW UPON THE HEAD,

SUCCESSFULLY TREATED.

By ISAAC PARRISH, M.D.

Read before the Philadelphia Pathological Society.

H. T—, the subject of the present note, is a young man, of about 20 years of age, tall and of slim stature, and of strumous constitution, having been at one time affected with necrosis of the tibia, from which he had recovered, with the loss of several portions of bone.

While engaged in his occupation, as clerk of a store, he had occasion to get upon a high counter, and in suddenly rising upon his feet, from a stooping position, struck his head with violence against the end of a gas-pipe, which projected from the ceiling. The blow was received upon the top of the head, two or three inches to the left of the sagittal suture.

He fell back in a state of insensibility, and, in a few moments, passed into a convulsion. A physician was immediately sent for, but when he arrived consciousness was returning; and nothing was prescribed in the way of medicine; the patient was cautioned, however, against undue exertion, &c. After the fit, severe headache continued, but the patient considered himself well enough to walk home, a distance of several squares.

On reaching the door of his chamber, in the third story, he uttered a loud scream, and fell prostrate on the floor in a violent convulsion. I was with him in a few minutes, while the attack was still upon him, and have seldom witnessed a more severe fit. The face was deeply flushed, head hot, eyes injected, pulse tense, with frothing at the mouth, and general muscular disturbance.

Ice water was freely poured over the head, and sinapisms were applied to the feet, and in a few minutes the attack subsided.

A large number of leeches were now applied to the temples, and the sinapisms were continued to different parts of the extremities, until the stupor following the convulsion had entirely passed away.

As consciousness returned, the pain in the head was still the subject of complaint; this, however, was greatly relieved by the leeching; the patient became calm and rational, and detailed with precision the particulars of the accident.

In about an hour, however, he broke out into incoherent conversation, screaming and laughing by turns, with hot head and flushed face; this quickly passed over under the use of cold applications, and he sank into a quiet, natural sleep. During this visit, the point of injury was carefully examined by shaving the head over the part, but nothing but a slight contusion could be discovered; the bone not appearing to be injured.

The accident occurred Seventh mo. (July) 31st, 1839, in the afternoon. During the night the patient slept calmly, but on the following day he had several attacks of severe headache, coming on suddenly, and attended with screaming, laughing, &c. as above described. During several of these, he was insensible for a few minutes; but was generally easy and tranquil in the intervals between them.

He took several doses of a decoction of senna and Sulph. Magnes. during the day,

which purged him freely; the cold applications were continued to the head, and he was kept upon a low diet.

On the following day, eighth mo. (August) 2d, the attacks were less frequent and severe, and in two or three days they subsided altogether. The patient was carefully excluded from all causes of excitement, being kept quiet in his chamber, and restricted in his diet, until all headache and uneasiness had entirely left him, when he was allowed to go abroad cautiously, without, however, engaging in any business, and being restrained as far as possible from everything which might excite his nervous system.

For a period of eight months the patient escaped a renewal of the disease; and it was hoped that he had entirely recovered from the predisposition. He suffered, however, from another attack in the fourth mo. (April,) 1810. It came on during the exercise of singing at a place of worship; and, from what I could learn, resembled very much those which had preceded it. From this time the susceptibility to the disease increased, and the attacks recurred at shorter intervals. Any sudden fright was apt to induce it; on several occasions the noise of the firemen and the ringing of the bells brought on a paroxysm. The patient was sent to the country with a view of improving his general health, and of separating him from those causes which seemed to excite his malady.

He remained out of town several weeks, during which time he was clear of the convulsion; on his return, however, they recurred, and were so frequent and distressing as to cause his friends great anxiety, and to render it unsafe for him to go abroad alone.

It was now remarked, by those who witnessed these attacks, that they were immediately preceded by a shoot of pain in that portion of the head which had been the seat of injury; the patient would seize his hair over this spot, and pull it forcibly, as if in agony, and then pass into a convulsion.

No pain in the head was complained of at any other time, nor did the patient seem aware that any connection existed between these attacks and the blow he had received. On close examination of the injured part, however, it was very evident that there was a sensitive point, although nothing externally indicated it. Pressure upon a spot about the size of a quarter of a dollar piece, a little to the left of the sagittal suture, caused severe pain and general nervous agitation, and indicated with sufficient clearness the close connection between the convulsions and the injury which this part had sustained. This was evidently the point from which the *aura* arose, and at once assumed an important place in the subsequent treatment of the case.

A consultation was now requested, and

that excellent and experienced surgeon, Dr. Thomas T. Hewson, joined me. After a careful review of the history of the case, it was determined to address our remedies chiefly to the original seat of injury; it was believed that the acute pain on pressure, and the evident suffering prior to a paroxysm, felt at this spot, furnished sufficient indications for such a course.

Eighth mo. (Aug.) 1st, 1810—just one year after the reception of the injury—assisted by Dr. Hewson, I made an incision about two inches long, directly through the tender portion of the scalp, and down to the bone. Several issue peas were inserted between the edges of the wound, and secured in their places by plaster. In a few days purulent discharge took place, and a constant drain was thereby established from this irritated surface. A course of constitutional treatment, with tonics, salt bath, &c. was at the same time instituted, and we had the gratification of witnessing a rapid amendment in our patient; no return of pain or convulsions occurred, and his general health improved.

About a month after the incision into the scalp, the patient was attacked with severe periostitis in the limb which had previously been the subject of necrosis. Leeching, anodyne plasters, &c. relieved this affection in a degree.

At the end of seven weeks, the soreness in the scalp having entirely disappeared, it was deemed safe to remove the peas, and heal up the issue. A seton was passed over the tibia, which continued painful at times; this was kept discharging for several months, until all pain in this part had disappeared.

Our attendance upon the patient now ceased, although we did not consider him safe from a recurrence of the convulsions. He has, however, escaped entirely up to this time—a period of between two and three years—thus giving us the opportunity of reporting his case as cured. When we consider the frequency of the attacks prior to the issue in the scalp, and the entire immunity from them since that time, notwithstanding the constant exposure of the patient to those causes which formerly induced them, we must regard this procedure as a highly interesting and important curative measure—at least in the present instance.

Remarks.—The great obscurity in which the pathology of epilepsy is involved, and the inefficiency of all known medical means in its treatment, at least in the large proportion of cases, renders the report of every case in which remedies have proved availing a matter of some importance.

The case now presented offers an interesting example of that form of epilepsy termed by the old writers *sympathetic*, in which the brain appears to be involved secondarily—

the paroxysm taking its rise from a point *without* the cranium. This variety has always been considered more manageable than that which has its origin in some hidden cause *within* the brain, whether induced by hereditary predisposition, or from a constitutional vice of any kind. Hence Hippocrates has sagaciously remarked that those epileptics are very hard to be cured "in whom the disease affords no sign from what part of the body it takes its origin;" and Celsus has said with equal propriety—"that if the whole body is affected at once, and no sense of the approaching fit is felt in any particular part, but the person falls down unexpectedly, of whatever age he is, he can hardly be cured." Many similar expressions might be quoted from ancient authors, tending to show the importance which they attached to this distinction between ilioptatic and sympathetic epilepsy—a distinction which appears to have been too much overlooked by modern practitioners, except in cases where it is so obvious as to force itself upon our attention, as in fits occurring in infants from dentition, from indigestible matters in the alimentary canal, &c. Points of local irritation upon the surface of the body may be as influential in inducing an epileptic paroxysm as internal causes, and, by removing them, we may be equally successful in putting a period to the disease.

Hence the importance of close inquiry into the history of each case, and if a centre or point be discovered from which the aura epileptica takes its origin, our remedies may be directed to it with a hope of success. The application of blisters, issues, and even of the cautery, to such diseased parts, are strongly recommended by the old authors, and many cases are reported in which they have been successful.

In some instances the occurrence of a spontaneous discharge of matter from the head, the appearance of an eruption, or an accidental wound of the scalp, have accomplished a cure. Thus we find in Van Swieten's Commentaries, the case of a French nobleman related who, being troubled with an epilepsy, took a journey into Italy, in order to consult the most skilful physicians there; but being plundered by robbers upon the road, and very much wounded, he was left for dead: besides other wounds, he had received a very large one in his forehead, which carried off a great part of the bone. After a long time, he was cured of this wound; and, at the same time, was freed of the epilepsy, which used to return upon him every month*."

The use of the trepan, in certain cases of epilepsy following injuries of the head, was also recommended by the ancients—espe-

cially when the symptoms indicated disease of the bone, or the extravasation of humors under the skull, or pressure on the brain from a depressed fragment. This operation has been revived in this country by Dr. Dudley, of Lexington, who has reported several very interesting cases of cure after its performance. Dr. D. very judiciously restricts the resort to so serious a measure to those cases only in which there is an evident depression of bone, or a morbid condition of it, produced by violence or other causes, leaving thereby but little doubt as to the point to which the instrument should be applied, and of the practicability of removing the cause upon which the cerebral excitement depends.

Dr. Dudley also believes that chronic inflammation of the pericranium is not an unfrequent result of contused wounds of the scalp, which have been healed too rapidly by the first intention; and that many unpleasant and alarming symptoms are the consequence of this practice*."

The case now narrated would seem to favour the idea that chronic inflammation of the pericranium may even induce epilepsy, and that the establishment of a drain over the diseased surface affords the best means of relief.

Nor is it irrational to suppose that the same practice might answer even in cases where the bone itself is diseased, without a resort to the trephine, provided the internal table were not involved in the mischief, and no pressure existed upon the brain.

Painful affections of particular nerves, coming on in paroxysms, and arising from disease in the trunk of the nerve, whether induced by injury or from other causes, are sometimes the cause of convulsions, which, if not arrested, may become habitual. Under these circumstances, division of the diseased trunk is obviously indicated, and has been long practised. A very curious case of this kind is related in the learned Commentaries just quoted. "A woman, of thirty-eight years of age, had been twelve years subject to the epilepsy: in the beginning of the disease she had a paroxysm every month; afterwards it so increased that she suffered four or five strong fits every day, each of which lasted for an hour and upwards; whence, being rendered quite dull and stupid, she was no longer able to take care of her family. All kinds of remedies were used without the least success, the disease still growing worse.

In the meantime, the paroxysm always began in the leg, about the lower part of the gastrocnemii muscles; immediately it flew up to her head; and then she fell down violently convulsed, and foaming at the mouth.

* Van Swieten's Commentaries, vol. x. p. 425.

* Transylvania Journal of Medicine, vol. i.

A physician, who was present during the time of paroxysm, compared the leg affected with the other, and he could not distinguish any difference between them: however, he boldly thrust in a scalpel to the depth of about two inches, and in the bottom of the wound he found a hard, cartilaginous body, somewhat larger than a pea; he separated it from the muscles, and found that it rested upon a nerve: cutting the nerve, he laid hold of that heterogeneous body, and he pulled it out; this was no sooner done but immediately the patient recovered out of the fit, saying that she was very well, and afterwards lived quite free of this terrible disease, and recovered her former vigour both of mind and body*."

The facts thus hastily thrown together sufficiently prove the position that a small point of local irritation, which might readily escape notice, may prove the source of this terrible disease, and that it becomes the physician to investigate closely the history of each case.

That many cases of idiopathic epilepsy occur which are entirely beyond all known means of cure, is lamentably true; while it is possible that cases deemed hopeless might be relieved were physicians more accurate in scrutinizing them.

It may be remarked, in addition, that the practice of making an incision through the scalp over the sagittal suture, and of inserting the issue peas with a view of establishing steady counter-irritation in this situation, has been employed for some years past by Dr. Charles Evans, in the treatment of chronic affections of the brain, with very satisfactory results. The extensive opportunities enjoyed by Dr. Evans for observation on these diseases, as physician of a large insane hospital, renders his experience upon the question very valuable†.

THE

LATE ABRAHAM COLLES, Esq. M.D.
Dublin.

(From a Correspondent.)

WITH unfeigned sorrow we have had to announce the decease of Abraham Colles, Esq. M.D. during a period of thirty-four years Professor of Surgery in the Royal College of Surgeons, and for upwards of twenty the acknowledged head of the surgical profession in Ireland. This pre-eminence he enjoyed, as well by the decision of the public, evidenced by the vast extent of his practice, as by the judgment of his professional brethren, attested by numerous tributes of their admiration and esteem. Mr. Colles

was a singular example of the attainment of the highest rank and honour, without having excited the jealousy of a competitor, or made an enemy by his success. If he were dearer to one class more than to another, it was to the junior branches of the profession, who not merely looked up to him as an experienced and eminent instructor, but even regarded him with veneration almost filial. As to the last honours paid yesterday to his mortal remains, they were the spontaneous expression of the feeling common to all who knew him, whether in his public capacities or in the relations of private life. The ashes of but few men, in our time or memory, have been accompanied to the tomb by a longer train of mourners, for the homage thus offered to his talents and virtues was as extended as the sphere of his professional exertions. He was widely known, and as widely respected, and we believe no man in this country had a more numerous acquaintance, or could count in the number so many devoted friends. This is not the place or the occasion for minute biographical details; suffice it to say that the career of Mr. Colles was of indefatigable activity; beginning with but little means, few friends, and no patron, he accumulated by persevering, independent, and untiring industry, an ample and an honourable fortune, and the highest reputation. No man ever brought to the science or practice of his arduous profession, a finer combination of the many intellectual qualities it requires: that enthusiasm so essential to success in any pursuit, he possessed in a remarkable degree; to this he united a soundness of judgment, and a nervous, masculine understanding, which preserved him from every speculative delusion, and mainly contributed to the confidence he inspired, and the solid reputation he enjoyed. As a lecturer, he was as highly estimated by the faculty as he was valued by the public for his practical talents. The perfect appropriateness of his style and manner to the subject-matter of his addresses, justly entitled them to the praise of eloquence, and when, in 1836, he retired from the chair of surgery, which he had so long filled with ability and applause, the discharge of his duties in that office was pronounced by the unanimous voice of the Royal College of Surgeons "as the principal cause of the success and high reputation of the School of Surgery in Ireland." On that occasion, that eminent and public spirited body waited upon Mr. Colles at his private residence, and presented him with a most complimentary address, as honourable to their feelings as it was gratifying to his own, as also a magnificent piece of plate, and which, by his last will and testament, he has bequeathed in an especial manner as an heirloom to his family. In politics Mr. Colles was a liberal; that party had no adherent

* Van Swieten's Commentaries, vol. x. p. 483.

† From the Philadelphia Examiner Vol. vi. No. 2.

more devoted, more upright, more unselfish. In his latest days he looked back with proud and well-founded satisfaction to the support he had steadily given through life to the cause of Catholic Emancipation, and to every great question affecting the peace or liberty of Ireland. When his political party was in the shadow, it had no more faithful friend, none more ready to take his share in every exertion it required, and in every sacrifice it exacted; but when the sun returned, he neither participated, nor sought to participate in the prospects or the advantages that returned with it. The satisfaction with which a good man witnesses the triumph of principles he believes to be sound and virtuous, he felt and he enjoyed; but his enjoyment was more than disinterested, for he was not only no solicitor for the favours of the Whig government, but when in the distribution of high honours amongst the members of the medical profession, they most unaccountably overlooked his paramount and transcendent claims; whether it was neglect, or whether it was error, it never excited his displeasure or ruffled his tranquillity. Personal considerations had not attached him to the party, and personal slight could not detach him from it. He died as he lived, an honest politician, and an honest man—his motives pure, and his reward the testimony of an approving conscience, the fame that attends true philanthropy, and the disinterested love of truth and justice. In private life, the kindness, the usefulness of his nature, the cheerfulness of his temper, the simplicity of his manners, were attractions and endearments that will long be remembered by all who knew him, whether in his medical capacity, in the social sphere, or in the domestic circle. He has left behind him no gentler or sweeter private character. An acute observation of the world, a sagacious insight into human nature, manly sense, extended information, and a vein of peculiar good-natured pleasantry, were amongst the qualities that made his society most attractive, and his conversation most engaging. He formed his opinions with care, expressed them with singular but impressive modesty, and no man ever embraced or enforced an opinion or a tenet with more complete absence of bigotry. His experience and sound understanding rendered him a valuable counsellor in every affair of life, but he was even ready at all times to assist with more substantial succour, when the necessities of a friend required his aid, or any urgent distress appealed for sympathy. It need scarcely be stated that Mr. Colles had applied the powers of his strong and acute mind to that most important of all subjects, and of all earthly considerations. His respect for true religion was in direct proportion to the aversion in which he held hypocrisy

and fanaticism; he entertained a rational and sober, but firm and sincere conviction of the great truths of Christianity; and it was in these, and not in the mere retrospect of a well-spent life, that he found calm consolation in his last hours; his reliance of a blessed immortality being firmly placed on the sure and certain hope of the sincere and faithful christian.

OVARIAN OPERATIONS.

(From a Correspondent.)

WE understand that Mr. Walne not long since put to the test the safety and value of the tentative or preliminary section in ovarian operations. He had ascertained satisfactorily its utility by employing it in each of the three successful operations, by the large abdominal section, published in the *MEDICAL GAZETTE*, and since re-published, with additional details and practical remarks, in a separate form; but the cases having presented no obstacle to the completion of the operation, afforded no positive evidence of the safety with which it can be used in instances which prove so complicated that it is desirable not to proceed with the main undertaking. As far as one case in his hands goes in proof, he has now gained assurance of the safety of this proceeding; having desisted at this stage of an operation in consequence of adhesions of wide extent, between the peritoneum of the abdominal parietes and of the cyst, being found to exist. The patient was tapped some days after, has been so again, and is quite as well as she would have been had no operation been attempted; but she appears earnestly to regret that, at all hazards, extirpation had not been completed.

An operation has also been performed by Mr. W. with a fatal result. The case was one greatly complicated, and the disease, in the opinion of the lady's own medical advisers, would probably have put a period to the patient's existence in a few weeks, even if no operation had been performed. The details are said to be replete with interest and instructive circumstance. They will shortly, we believe, be laid before the profession through the medium of the *MEDICAL GAZETTE*, but in the meantime have been less fully narrated at a large meeting of a Metropolitan Medical Society.

MEDICAL ELECTIONS.

To the Editor of the Medical Gazette.

SIR,

THESE are indeed days, as you astutely remark, in a recent leading article, charac-

terised by "the feverish hurry of modern existence."

We have clearly reached the "confusion point" in the social thermometer, and particularly as regards the present medical management of hospitals and dispensaries.

Until lately the medical officers of a hospital or dispensary were gentlemen, who, after having with much toil and trouble, solicited the suffrages of the subscribers, were when elected to assist in dispensing the benefits provided by such charitable part of the community, and were therefore to be considered instruments in their hands for such good purposes.

But now it seems as if things were to be reversed, and that each medical staff is to be an oligarchy, or even tyranny by commission, so to speak, and the governors, God save the mark, are humbly to bow to their judgment in all things, but more especially in the election of the persons who are to distribute the very means they pay for.

The elections now progressing at the two western hospitals are examples of this state of things, not to cite other instances of a less striking description.

Now, were these combinations always entered into with the singleness of purpose of those whose only objects are the promotion of science, the good of the poor, and the general furtherance of the welfare of medical charities, the goodness of the effect might in some sort excuse the cause, but when, I am afraid, that other and less worthy interests have weight, this state of matters requires some remedy.

Let each charity employ its medical officers to select, if they please, candidates to fill the offices of physicians, surgeons, &c.; but let no further collective influence be used by them, for I am sure that any such attempt at dominance over the body of subscribers at large will only tend to disgust them with medical charities, and will deprive the poor of assistance, and the community of valuable results derived from the existence of so many means of studying disease.

It will be in the recollection of many that some years since a similar interference caused the nearly total closure of the wards of a great metropolitan hospital.—I am, sir,

Yours obediently,

JUSTITIA.

CLINICAL OBSERVATIONS

ON

HIP-JOINT DISEASE.

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary;
Assistant-Surgeon to the Westminster Hospital.

WHERE you find many children collected together, and more especially where many have been ill fed and neglected, you have frequently occasion to see "hip disease." Considering, however, that we have in this establishment, in the different schools, usually not less than 500 children; and considering, too, that many of them when admitted are debilitated, or diseased, the number of cases of this affection coming under treatment is certainly small. The disease is one which demands the serious attention of every medical man, because for the most part it is a disease of early life; and if detected early, and properly treated, may frequently be subdued; but if neglected at that period, or improperly treated, the result is either incurable lameness, or the loss of the child's life by wasting abscess.

This disease, known as *coxalgia*, *morbus coxarius*, *luxatio spontanea femoris*, is commonly known among us as hip-joint disease; and we prefer either of the other terms to that of *luxatio spontanea femoris*, because if we succeed in treatment the luxation may never occur.

In the earlier period of its progress the symptoms are variable: there may be a dull pain in the region of the hip, but it may be absolutely wanting; and then it may be that a certain want of power in the limb, a certain tendency to limp, and a sense of stiffness in the morning, are the only symptoms which are observed. When the pain exists, it is usually at first not permanent; but it may increase towards evening, like rheumatism. When the pain becomes more fixed, it will not always be complained of at

the same point. Sometimes it will be most felt above, sometimes below, sometimes at the level of the joint; sometimes at the groin. When the pain becomes fixed, it is much increased by motion, and especially by pressure upon the trochanter. In some cases the pain is not severe at the hip, but is fixed at the knee-joint, or it may extend along the whole limb. When the pain is fixed at the knee-joint, or at the ankle, it is sometimes so severe as to mask the hip pain, and to mislead an ignorant practitioner. A case occurred to me some time ago in which the symptoms at the hip were so trifling, and those at the knee so severe, that the friends doubted the correctness of my opinion, and took the child a long way off to consult a man "noted in joint cases;" he placed issues about the knee, neglected the hip; in a few weeks extensive abscesses formed around the hip, and the child died. It has been suggested by more than one experienced surgeon that pressure on the knee in such cases does not increase the pain, and that that will serve to determine whether the mischief be there. My own experience does not confirm the value of that test. I have again and again known loud cries to be uttered in such cases upon pressure when there was no disease in the knee-joint. Again, it has been said that there is no swelling of the knee in such cases, but my own experience does not entirely confirm the correctness of this remark.

These symptoms may last for months, or even years, the patient being occasionally better and worse. The leg may be a little dragged, and the foot may be turned a little outwards. Sometimes from the first the symptoms are acute, the pain severe, with tumefaction, fever, and an inability to move the limb. In this place, not long ago, we had two cases, a boy and girl, who came under treatment early, who were bled, blistered, and cauterised, and the joint kept motionless, but the progress of the disease could not be arrested.

The three important symptoms, however, in the first period, are pain, apparent elongation of the limb, and the limping.

In the second period of the disease the symptoms are more strongly marked. The apparent lengthening of the limb continues, at the same time the flexor muscles of the leg are set in action, and the patient rests on the toes; the buttock of the affected side is flattened, the thigh is lessened in size and firmness, and the trochanter seems more prominent. Every movement which brings the articular surfaces in contact is now very painful; the whole weight of the body is therefore directed upon the sound limb.

The third period is characterised by shortening of the limb, whether there be luxation or caries. Usually the shortening is accompanied by the ordinary signs of dislocation upwards. The foot is rotated inwards, the trochanter is directed upwards and forwards. You may, however, see shortening without any change in the direction of the foot; but this is rare; it happens when the floor of the acetabulum gives way, and the head of the femur is jammed into it. You may see the apparent elongation suddenly become real; the head of the bone may be dislocated downwards into the thyroid foramen. This is also a very rare occurrence.

The third period in the progress of the disease is more strongly marked than either of the others. The limb is shortened, and sometimes there is an end of the disease; the pain diminishes, the head of the bone hollows out for itself a cavity; but there is incurable lameness. Most commonly, however, a painful tumor is formed around the joint; fluctuation is soon observed, and either it bursts, or is opened, and a quantity of pus escapes. It is at this time, according to Dzondi, that the pain at the knee becomes most severe. In most cases the opening becomes fistulous; in others it closes after a time.

If the child sinks under the irritation, the abscess having been opened, the appearances presented after death are very variable. The parts around the joint are often infiltrated with pus; the sinuses may communicate even with the joint; the capsule is more or less completely destroyed; the soft parts within the acetabulum are often tumid, so as to push the head of the femur out; at other times they are broken down and carried away. Sometimes the round ligament is destroyed; at others it is considerably elongated. The cartilage lining the acetabulum as well as that covering the head of the bone, is either softened or destroyed, and the bone itself is exposed and carious, and ankylosis may occur. In some cases the fundus of the acetabulum has given way, and the pus from the joint has found its way into the rectum. In one

of the specimens before you the acetabulum has lost every vestige of cartilage, so has the head of the femur; therefore there is no correspondence between the size of the head of the bone and the containing cavity: in another specimen the two bones are ankylosed. In other cases, while the acetabulum is nearly denuded, the head of the femur has scarcely suffered. In other instances it is the head of the femur which has principally suffered. And in these cases there may be a real though inconsiderable shortening, while the head of the bone is in the acetabulum. The head of the bone, however, is not unfrequently found on the dorsum of the ilium; it has been found on the thyroid opening.

You see that the appearances upon examination after death are very variable; and opinions on the subject are not less variable. If, when opportunities of making such examinations are so frequent as they are in the latter periods of the disease, the opinions are so discrepant, we might naturally expect that there would be greater differences with reference to the earlier stages of the disease, where the opportunities of investigation are unfrequent; and it is so. Thus, if we take that important feature of the disease, the lengthening of the limb, how differently is it explained. One man says it is owing to the pressure exercised on the head of the bone by the accumulated synovial fluid. This accumulation of fluid is by no means proved to be a common occurrence. Sir B. Brodie seems to have met with it only once or twice.

Although it is possible that at a particular time, in a particular case, there may be a slight elongation of the limb, it is certain in ordinary cases the elongation is only apparent. As soon as the patient begins to feel discomfort at the joint, he begins to spare that limb; he supports himself mainly with the other; the crest of the corresponding ilium is elevated above its fellow, and the limb of the affected side is, to that extent, apparently longer than the other, and the foot is advanced. This symptom may therefore, at an early stage of its existence, be dissipated by the patient keeping his bed a few days, but if it has existed long it may have induced a certain amount of curvature of the spine, and then the horizontal position may not so easily right it. It is certain, however, that cases of real elongation may occur when the head of the bone descends into the thyroid fossa; but this seldom happens.

However characteristic may be the ordinary symptoms of hip disease, every day we see that they are mistaken, particularly in the earlier stages of the disease. Let us now look more narrowly into the value of

the several symptoms. One of the earliest signs is a certain amount of pain or uneasiness; often it is felt during walking; sometimes it can be produced by suddenly pressing upon the trochanter or upon the heel, the limb being extended; sometimes it is severe. But recollect, the absence of pain is no proof that there is no mischief at the joint. An important feature is an apparent or real lengthening of the limb; but it is necessary to be very careful in making the examination, to determine this point. For this purpose various plans have been proposed: *e. g.* Place the patient on his back in bed: with a piece of tape measure the exact distance between the anterior and superior iliac spine, and the superior border of the patella; whatever be the inclination of the pelvis, if the distance be equal on both sides, the length of the limbs must be equal too. Some persons have desired to test the matter in other ways: the patient may be placed upon a chair in the sitting posture, as I now place this child, sitting so far back that the spine rests fairly against the back of the chair; we then take care that the legs are directed forward exactly parallel to each other. First we compare the two knees to ascertain whether one projects beyond the other; we then compare the two heels. Again, some surgeons rely most on an examination in the erect posture. My own notion is, that if there be any doubt we should try all; because when the signs are equivocal, the importance of correct diagnosis is most pressing. The standing posture enables us to observe the direction of the spine and the pelvis, as well as the prominence of the trochanter: this we do by standing behind as well as before the patient. This apparent lengthening is an important sign when associated with others, alone it is not worth much. Sir B. Brodie regards a flattening of the buttocks as one of the most constant signs of ulceration of the cartilages. That flattened appearance is accompanied by flaccidity, and it looks altogether larger than that of the opposite side. Usually, if not always, this flattening and flaccidity are the results of inaction of the gluteal muscles. Sir B. Brodie relies much on this sign to distinguish between ulceration of the cartilages and inflammation of the joint; in the latter case there is, he says, increased fullness, tumefaction. It would become me to differ with much hesitation from this opinion; but I confess I do not entirely coincide in its correctness; neither do I in the opinion that the amount and kind of pain is a test between inflammation of the joint and ulceration of the cartilages. At the same time I have no doubt that to him they are sufficiently distinctive signs.

There are diseases with which that of the hip is but too frequently confounded. Among

these are "congenital dislocation," rheumatic inflammation of the hip, and suppuration following caries or necrosis about the joint.

In congenital displacement the limb is shortened from birth. If we place the child on the bed, fix the pelvis, and pull at the leg, we can without pain elongate it, but when the traction ceases, the shortening is again quickly manifested; the head of the bone can be felt moving in the iliac fossa; there is no pain; the thigh can be freely moved, and the sole of the foot rests on the ground. We distinguish hip disease from rheumatism of the hip, by the character of the pain, which before it attacked the hip may have affected other parts. Chronic suppuration about the hip, following caries or necrosis, can be distinguished from that of hip disease, by the occurrence of less pain when the thigh is moved, by the continuance of the pain when the joint is at rest. Still you may have to do with complicated cases, which may present great difficulty; abscesses outside the joint have perforated its capsule, and other complications may occur.

The course, then, of hip disease is very variable; you have seen here cases where between the time of the first appearance of limping to the dislocation of the bone, only a few weeks have elapsed, and that in defiance of the most energetic treatment. There is a case now before us, where the boy has been under treatment many months; where the symptoms have abated, where the head of the bone is still in the acetabulum; but where slight motion, even now, would quickly aggravate the mischief. Indeed, it is astonishing how much we seem to be able to do in very chronic cases occurring in scrofulous children, by improved nutrition, and absolute rest of the joint, provided we can subdue the early and more urgent symptoms. But it is remarkable how long a time will pass in some cases before the evidence of mischief becomes very decided; and how large an opportunity we have for attempting to subdue the disease; how much in such cases good air and good food will do to relieve the patient. In many cases we are not consulted until the head of the femur is in course of being displaced, and all that is left for us to do is to endeavour to prevent suppurative action, and to keep the limb so far extended as to get a new joint formed as nearly as may be to the old one. In this we often fail: larger abscesses form, they may burrow through surrounding parts, open at several points, and the patient may be worn down by the discharges.

Some surgeons have entertained notions that they could at a comparatively early period predicate the probable course of the disease. Boyer thought he could point out

the direction in which the displacement would occur. He reasoned thus: when there is much elongation of the limb from the beginning, when the pain is great, with tumefaction of the upper part of the thigh, we may presume that the disease is owing to engorgement of the synovial gland, and the articular cartilages; that the head of the femur will escape by the upper part of the cotyloid cavity, and that it will glide upon the external surface of the ilium. Under opposite circumstances, it is more probable that caries will cause the displacement, which will then happen sometimes on the superior and external, sometimes by its internal and inferior border. When the affected limb, for some time much longer than the other, preserve its natural rectitude, and the faculty of exercising rotation, though with pain, and that abscess forms in any part of the thigh, we may presume that the fungus of the cotyloid cavity is carious, and that the disease may become mortal even though the bone may not leave the acetabulum. When the disease terminates in ankylosis, the limb retains the position which has been given to it. When the disease is cured by the formation of a new joint, a hollow is made at the point upon which the head of the femur rests; the head becomes flatter under this pressure itself, and smaller. And the surrounding structures are modified so as to be converted into a capsule.

In the greater number of cases we are unable to assign any evident cause of hip-joint disease; it seems to be the result of a debilitated constitution. In some cases, however, something occurs to set up a diseased action in this part, such as a fall or other injury done to the trochanter major, or the knee, or the foot, the limb being extended; but certainly we frequently see it after affections such as small-pox, or measles, which have still farther enfeebled an already weakly child, and when no direct injury has been sustained by the joint.

Now let us see what plan answers best for the treatment of this affection. Unquestionably absolute rest is of the last importance, whatever be the general and local treatment employed. Its good effects you could appreciate in the case of the child before us. When he came under treatment, you will recollect I thought badly of the case. I ordered him to be cupped, though pale and scrofulous; and I mentioned to you at the time, that I was less afraid than some people are to take blood locally in cases of scrofulous inflammation. There is always a certain amount of congestion, though the symptoms may not be active; and much relief is often afforded by such local abstraction of blood, and I have never known it produce any bad effects. He was afterwards blistered; the limb was kept immoveable by

the long splint; and you see the result. I have a strong conviction that, if motion had been permitted, the case would have done badly. The limb was kept motionless nearly three months; and after that it was only very gently moved for some time. If the limb be left at liberty too soon, all the good which may have been obtained from a month or six weeks' repose is soon dissipated. No doubt such a plan is very fatiguing, especially to young and restless patients, who cannot be convinced of the necessity for it; but it is a small matter to put in competition with the condition of a cripple for life. To maintain a complete repose for the joint many plans have been suggested—more or less modifications of apparatus for fracture of the neck of the thigh bone—and, generally, several months should elapse, before they should be laid aside.

This disease is so constantly associated with a debilitated constitution, often scrofulous, that particular care must be bestowed upon the general health. Good food, and sometimes tonic medicines, must be given to improve nutrition, which is commonly defective. Good air is no less essential; but about this there is often difficulty, from the necessity of keeping the limb fixed in extension. The rich man's child can have carriage exercise in the open air; while the poor man's child is commonly doomed to its narrow room: this is one of the privations which poverty brings with it. I have already stated that I am favourable to the local abstraction of blood, even in pale, flabby, scrofulous-looking children: the quantity taken each time may be small—even a couple of ounces once a week—while you fortify the general health. In many cases, where the health of the patient is good, and the symptoms acute, a larger quantity of blood may be taken at a time. When the acuteness of the symptoms is subdued, counter-irritation should be steadily kept up, either by means of perpetual blistering, caustic issues, setons, moxas, or the actual cautery. If we employ the first agent, we should repeat the blister every six or seven days, until all pain is dissipated: it is therefore better to apply circular blisters of not very large size around the joint, so as to keep up the irritation as long as possible on sound skin. Some surgeons prefer to apply one large blister, and keep it open. Setons and issues are unquestionably more energetic counter-irritants than one, or even two blisters; but I do not think they are so powerful in their action as a succession of blisters. Besides, both issues and setons are often very troublesome: the granulations on the issues become fungous, and push out the peas; a similar fungous condition of the seton is very common; and in both cases the discharge from them becomes ill-conditioned, and all salutary in-

fluence is destroyed. Besides, I think the discharge from such new surfaces, when long continued, ceases to be useful: I think them much more efficacious when frequently renewed.

Some surgeons are content, after cupping, to rely much upon comparatively mild means, such as lowered diet, warm fomentations or baths, diaphoretics, tartar emetic, and opium—indeed such means as might be employed in more superficial inflammatory action. It is true they employ these means in the first period, and, if necessary, resort to counter-irritation subsequently, such as tartar emetic ointment, blisters, setons, cauteries. My objection to the freely antiphlogistic treatment, even in the first period, is this: a large portion of those suffering from hip-joint disease are weakly serofulous children; any general treatment which tends still farther to lower them is clearly wrong, because inflammatory action becomes additionally mischievous where the powers of life are already depressed. I am always prepared to act with vigour locally; but, for the reasons I give, I do not approve of any means which have a direct tendency to lower the powers of life.

Rust carried out farther than any one I know a very energetic plan of treatment locally—the actual cautery, which he used in the first stage of the disease, but after having removed blood from the part by cupping or leeching. His plan was to use the cautery as soon as there was evident apparent lengthening. His cautery had converging rays—either three, four, or five, according to the age of the patient and the effect sought to be obtained: the largest ray was applied along the course of the sciatic nerve, the next immediately behind the great trochanter, the third directly over the great trochanter itself. The extent of the cauterization depended on the condition of the patient.

Few men would be found to deny the great value of the actual cautery: but only a very few have the courage to use it. Every surgeon knows that we employ, without any hesitation, much more painful means; but few patients will submit to the remedy if they can help it. Most, if not all, of the good effects of the actual cautery may be obtained from moxas. I believe they are more painful than the red hot iron, which is unquestionably very severe for a moment; but I have no question that the gradual burning by moxa is worse. Still a patient would not object to the one, while he would refuse to submit to the other. In neither case do I think a slough should be made. I think counter-irritation is most effectual when the skin is entire; and therefore, in either case, I only allow the agent to remain in contact long enough to produce a yellowish

horny hardening of the skin; but this I do, at the same time, at several points around the joint.

When, spite of our treatment, large abscesses form, men are not agreed as to the proper plan of treatment: some surgeons open them early; others wait until the pointing is decided. It is not easy to decide between them. Small collections of pus are now and then absorbed under counter-irritant treatment; larger collections are apt to burrow, and break down surrounding tissues. Then, when we determine to open them, there is as much difference of opinion as to the means of doing it. If we make valvular openings, and quickly close them up, the cavity will fill again; and although we may block up the opening quickly two or three times, in the end it becomes fistulous; hectic fever may come on, and death. Suppose you make a free opening with a knife, or caustic, you are no better off; and in many cases constitutional disturbance quickly follows. I think, therefore, it is wisest to keep up energetic irritation in the neighbourhood, and keep the cavity close as long as you can; but most cases do badly.

If the symptoms abate, the quantity of pus being lessened, and the fluid assuming a better appearance, and the slough being kept up, the patient may gradually recover. In that case you must be particularly cautious to keep the parts as quiet as possible; for apparently very trifling causes will light up severe mischief.

A question has been much considered of late years: it is, whether, when every thing is quiet, any attempt should be made to replace the head of the bone in the acetabulum. To enable us to decide properly in this case, we should know what has happened to the acetabulum. Most surgeons are of opinion that the cavity becomes filled up. Cases are recorded where it has remained very little changed. Some persons having assumed this to be the common condition, many attempts have been made to replace the bone, by extending the limb until the head of the bone is brought to what is conceived to be its proper position; it is maintained there for a long time, and at last it becomes adapted to its new position. Much doubt seems to be entertained whether we can expect to succeed, though cases have been exhibited in which the treatment was, it is alleged, successful. I have never known any thing sufficiently decided or encouraging to induce me to recommend it for your adoption.

ON THE
AVERAGE NUMBER OF DEATHS
IN CAPITAL OPERATIONS.

To the Editor of the Medical Gazette.

SIR,

I SHALL be obliged by your inserting in your journal the results of operations during a practice of twenty two years. What led to their arrangement, &c. is fully explained in the paper.

I am, sir,

Your obedient servant,

JOHN P. HALTON,

Fellow of the Royal College of Surgeons of
England, and Surgeon to the Liverpool
Infirmary.

74, Mount Pleasant, Liverpool,
Dec. 8, 1843.

In lately reading over the reports of several cases in which ovarian tumors had been removed, I have remarked, that the advocates of that operation, recommend it as "a perfectly legitimate and more than ordinarily successful operation," and in their zeal to enrol it among the legitimate and established operations of surgery, have used arguments which appear to me tending to detract from the success, and consequently the safety and value, of all the established capital operations, which form the constant routine of hospital practice.

Far from desiring to withhold from these gentlemen the praise due to their exertions to relieve, by operation, the subjects of ovarian enlargement, from a disease for which they believe no other means of relief can be relied on, I cannot but regret that they should, at least, have the appearance of attempting to exalt this operation in the estimation of the profession, at the expense of all other capital operations, by a sweeping deterioration of their success.

I cannot pretend to estimate the opportunities these gentlemen have had, either of performing or witnessing the performance of the great operations of surgery, or how they have arrived at such conclusions as to the results, unless it be from the limited reports hitherto published; but certainly, I must console myself to have been so startled at their assertions of the unfavourable results of all established capital operations, differing as they did with the impression on my mind of the

experience of my own practice, that I resolved to refer to the records of the last twenty-two years; the first period of four years and a half being occupied as surgeon to the Dispensary, the latter of nearly eighteen years, being engaged as surgeon to the Liverpool Infirmary: the examination proved the correctness of my impression.

Mr. Phillips, in a paper read before the Royal Medical and Chirurgical Society of London, Nov. 14, 1827*, "as to the correctness of the returns upon which his statements were founded, some doubts were expressed," states: "It has happened on several occasions, that the medical men to whom I have applied for results of their individual experience, have at once said, 'I very rarely lose a case after amputation,' and when they have referred to their own notes, or to the hospital records, where such a thing was practicable, they have been astonished at the extent of the mortality. These circumstances alone would be sufficient to shew the fallacy of resting our belief on vague impressions, and the necessity of some more exact evidence upon which to found opinion†."

This is not my case; the examination has proved that I had not been led astray by any "vague impressions;" on the contrary, that my impression fell short of the actual amount of success, and it created a strong inclination to give the result to the profession.

I hesitated, however, as to the mode in which this should be done: to give a detail of the number of operations performed, appeared to me so very like an advertisement, anything bordering on which I have always deprecated and so studiously avoided, as in many instances to have fallen under the censure of Mr. Phillips, when he says, "if the practitioner suppress successful cases an unfavourable impression may attach to beneficial practice‡." To this omission I must plead guilty; entirely from this feeling I have neglected to communicate to the profession many interesting cases, attended with successful results from operations, which I have been told ought to have been published.

I fully estimate the sentiment of

* MEDICAL GAZETTE, June 9, 1838, p. 457.

† *Ib.* p. 458.

‡ MEDICAL GAZETTE, October 9, 1840, p. 83.

Mr. Phillips, when he says, "I feel strongly the importance of recording on a large scale the risk attendant upon the performance of all operations*." And though I do not quarrel with him for being anxious for a record of the *risk*, I could have preferred his being desirous for a record of the *success* attendant upon the performance of all operations.

The risk of an *established* operation, I believe to be, in itself, small. Is it not the absence of risk which establishes the operation? The risk appears to me to lie in the manner in which it is performed: and if the profession, in its estimate of the value of operations, is to be influenced by the success attendant upon them, I agree with Mr. Walne, "when he would limit the performance of so formidable an operation as extraction of ovarian tumors, to surgeons qualified by habits of operating, &c.,"† he clearly believing that some portion of the risk lies in the manner in which it is performed.

This would prove a matter for serious consideration, in the event of obtaining "a record on a large scale of the risk attendant upon the performance of all operations;" for it would by no means be a fair criterion of the value of an operation, if failures which could clearly be proved to arise from the *mode* in which the operation had been performed were included in the record! For example, is the average of success from the operation of ligatures on large arteries, to be damaged by the registry of an operation for tying the branchial, in which the limb gangrened, and upon examination after removal it was found that the median nerve had been mistaken for the artery and tied, which necessarily proved unsuccessful? or, is an unsuccessful operation of ligature on the subclavian for aneurism, wherein it was found one or more of the cervical nerves had been included in the ligature, to be taken into the account? or, are unsuccessful operations which have been undertaken by young surgeons, after the proposals for operation had been condemned as unjustifiable by men whose station and experience in the profession afforded them the best means of judging of their practicability and success? All these examples have occurred in my own

knowledge, and how many more such instances might be added to the list, I do not know: perhaps Mr. Phillips had some such cases in view, when he stated, that "very few members of the profession are at all aware of the extent of mortality consequent upon surgical operations*."

Fully agreeing then with Mr. Phillips, in the importance of having a general record of all cases of capital operations, I cannot but believe, that were such obtained, judging from my own experience, and the success of those with whom I have been associated in hospital practice, he could have much other foundation for the remark, or that such assertions as the following would pass current.

Alluding to the operation of removal of ovarian cysts, he says, "I think no one can doubt that an operation which under adverse circumstances has succeeded nine times out of twelve cases ought to be resorted to, &c.†" "We do not hesitate to have recourse to the ligatures of large arteries, and regard it as a justifiable operation, though the results are much less favourable; we do not object to perform amputation of the thigh, although nearly two out of five die‡."

Dr. Clay says, "when compared with the results of other capital operations, lithotomy, lithotripsy, and even amputation, it stands in a far more favourable position, and it is a very strange prejudice indeed, that can admit those capital and more frequently fatal operations above mentioned, as legitimate and advisable, whilst one less fatal is summarily condemned."†

These premises I believe to be inaccurate; my individual experience is decidedly at variance with them, as will be found in the sequel.

Having consulted with a medical friend, on whose judgment I could rely, upon the propriety of giving to the profession the results of capital operations during a practice of twenty-two years, he was of opinion, that I could not only with propriety do so, but that the publication might be attended with advantage to the profession, as it would probably induce other hospital surgeons to follow the example, by which means we might ultimately obtain the important general record the

‡ On Extirpation of Diseased Ovaria.

want of which is so much felt at this crisis, to correct, the what I believe to be, erroneous assertions put forth to the disparagement of operative surgery.

I therefore no longer hesitate, but before entering on the statement, I may as well premise, that it is derived from a careful perusal of open records kept by my pupils, some of whom are now settled in practice in the town or neighbourhood, and who, were it necessary, could attest to their accuracy. For the reason already stated, I shall withhold the number of capital operations performed, and confine myself to a detail of the class of operation, and the average result from each, with a brief outline of the cases of death.

My present limits will not admit of my entering into an examination of the different results between primary and secondary operations in cases of amputation. And as to instituting a comparison between immediate and consecutive union, I may remark, that in my experience of the Liverpool Infirmary (thirty years) I never remember any other treatment than union by adhesion being attempted. To accomplish this, great care has always been taken in the first adaptation of the flaps (for the flap operation has been the almost invariable practice, as will be hereafter described), and such an anxiety has in many cases been manifested to obtain it, that the irritation of sutures has been avoided, the flaps being lightly adjusted and sustained in approximation by strips of plaster, in the composition of which resin formed no part.

Still, I consider the remarks of Mr. Phillips on this subject* admirable, and the modification he recommends well worth the consideration of all operating surgeons.

For the information of those who cannot be expected to appreciate what opportunity may have been afforded to warrant my appearing before the profession under such circumstances, I may quote the report of some part of the surgical practice of the Liverpool Infirmary, as returned to the Committee

of the House of Commons in 1834. It was required to state the number of capital operations performed by the three surgeons, Mr. Bickersteth, Mr. Dawson, and myself, in the previous four years, and the number of severe accidents and cases of fractured bone; of the latter, one thousand four hundred and eighty were returned, and two hundred and twenty capital operations.

In forming the average of death, I have not adopted the mode peculiar to some of the records of the operations for the removal of ovarian tumors, viz. confined myself to the result of "well selected cases," and where a death occurs placed it in a "different category." To this I object equally with the writer of the article in Dr. Forbes' British and Foreign Medical Review, for October last, p. 392, "as by no means a fair mode of estimating the result of the operation" or any operation. Were this example followed, I should of course have only to record a series of uninterrupted success for the last twenty-two years.

I conceive, if there be any advantage in the record of the results, it will consist in the publication without reservation of the results of all cases which of necessity the surgeon has been called upon to treat, however little the prospect afforded of success; and this I shall proceed to do.

With the imperfect statement as yet before the profession, as to the results of all the operations which have been performed for the removal of ovarian tumors, I find it difficult to arrive at a correct estimate of the safety, success, or value of this operation. It is very encouraging to hear of a few successful cases, but to form a safe conclusion we should have the particulars of the successful and fatal cases, place them side by side, and enter into an analysis of the merit or demerit of the minutiae which appeared either to promote success, or to contribute to the fatal termination.

The operations I have to record, comprise

- | | | |
|--|---|--|
| 1 Amputations of the thigh and leg, and arm, above and below the elbow | { | In cases of disease of the joints or severe compound fracture, with a view to save life. |
| 2dly. Amputation of portions of the foot and hand | | To save such remainder as would render them tolerably useful afterwards. In cases of compound fracture and laceration, occasioned either by being drawn in between the wheels of machinery, or otherwise crushed, or resulting from the bursting of fire-arms. |

- | | | |
|---|---|---|
| 3dly. Excision of joints, either complete or partial, of the knee, ankle, and elbow | { | In cases of compound dislocation of the joints, complicated with fracture of the bones entering into their formation, with a view to save the limb. |
| 4thly. Lateral operations on the bladder | | { To remove foreign body or stone |
| 5thly. Ligatures on large arteries | | In popliteal and subclavian aneurism. |
| 6thly. Operations for strangulated bowel. | { | In femoral, inguinal, and scrotal hernia. |
| 7thly. Amputation of portions of bone | | { In the varied cases of compound fracture, with a view to save the limb. |
| Lastly. Removal of tumors. | | Scirrhus, osteo-sarcomatous and carcinomatous. |

In amputations of the thigh, I have to record *one death in eleven*. The assertion to which I object is, that "nearly two out of five die."

In analysing the deaths, I find that the cases in which it was deemed necessary to amputate were persons whose limbs had been shattered by entanglement in the wheels of machinery, or smashed by the passage of railway carriages over them, or resulting from falls from lofty buildings.

Surgeons who have been accustomed to see such accidents need not be reminded of the amount of shock under which the vital power labours in such cases. The operation of amputation, though deemed a justifiable and necessary one, under such circumstances, cannot be relied on as affording much prospect of success. For instance, one of the deaths which reduce the average of success, resulted from a complication of injury received in consequence of a fall from a high building on to a flagged parapet; viz. considerable contusion of the elbow-joint and head, with concussion of the brain, accompanied with compound fracture of the thigh laying open the knee-joint, and simple fracture of the same leg. At the earnest solicitation of the friends, who hoped the removal of such a frightful mass of destruction might afford a chance of recovery, amputation was performed.

In the amputations of the thigh, the double flap operation, before and behind, was adopted, making the anterior flap the longer of the two in order to allow of its falling over the end of the bone, by which the line of the cicatrix was carried behind it. This mode of making the flaps in thigh amputations was adopted by Mr. Bickersteth, my colleague at the Infirmary, and my ex-

perience of his operations, which extends over a period of thirty years, warrants me in stating that his success has been great.

The peculiarity consists in making the first incisions through the integuments only, which are allowed to retract, and if necessary from the bulk of the limb, are dissected back a little. The division of the muscles is effected by transfixing the thigh with the cat-line, introducing its point at the nearest angle of the first incision, and bringing it out behind the bone at the opposite angle; it is then swept boldly out in a direction corresponding with the line of flap; the division anterior to the bone is made in the opposite direction from without to the angles of the flaps of integument; the stumps are excellent.

We are indebted for the adoption of the flap operation to Mr. Alanson, who was surgeon to the Liverpool Infirmary twenty-four years, from 1770 to 1794: since his time the flap operation has almost invariably been performed at the Liverpool Infirmary.

In amputations of the leg, I have to record *one death in six*.

In this average, success is very much reduced by the death of five cases in which amputation afforded but little hope of saving life. Three of the cases whose ages were between sixty-three and seventy four, were compound fracture complicated with great comminution of bone, and extensive laceration and destruction of the soft parts, and exhibiting evidence of great influence of shock on the vital power. One, a youth of eighteen, reduced to the last degree by scrofulous disease of the ankle-joint; the operation was performed with but little hope of success; he survived only three days. The fifth

case was compound fracture of both legs, and frightful laceration of the soft parts; indeed, the limbs were all but severed by entanglement in a mill-wheel. The shock in this case must have been intense; still sufficient vital energy remained to induce the trial of immediate amputation: he bore the operation better than was expected, very little blood was lost; he fainted on removal to bed, but soon rallied with the aid of the usual stimulants, and died nine hours and a half after the operation.

In amputations of the arm, above and below the elbow, I have to record one death in eighteen.

In this calculation the average of success is reduced by one case, in which amputation was only performed at the earnest request of the poor fellow, who was brought from a distance expressly to have the limb removed. He was so emaciated by the suffering incidental to disease of the elbow-joint, that little or no prospect was entertained of his recovery. He lingered nine days after the operation without any attempt at restoration being manifested, and upon examination of the stump after death, the flaps fell asunder spontaneously; no attempt at union had been made. The causes of death in the other cases not explained.

In amputations of parts of the hand or foot, the deaths were *one in thirty-six*.

The causes of death, tetanus or gangrene.

In the operations of excision of joints, partial or complete, of the knee, ankle, or elbow, the deaths have been *one in seven*.

Of the deaths, one case was a female, aged 72: a cart had passed over both legs, producing compound dislocation of one ankle, and simple dislocation with great contusion of the other. In the other cases, the severity of injury was so great that amputation afforded the only chance of recovery, but being objected to, excision of the articular surfaces was then resorted to under unfavourable circumstances.

In the after treatment of these cases, it is no uncommon occurrence for the first dressing, consisting of lint saturated in the patient's blood, to remain on until the wound is healed. I may mention one remarkable case, a com-

pound dislocation of the ankle (the internal lateral) with much comminution of bone, in which twenty-five pieces of bone were taken out, varying in size from that of a small walnut to a small pea, and in which the first dressing remained on nearly nine weeks; when it fell off, the wound was found healed. The after treatment consists in damping the bandages in the neighbourhood of the first lint with any cool application, sometimes cold water or very weak spirit lotion, as the case may seem to require.

I may, perhaps, be permitted here to mention, that there is at present in the Infirmary, under the care of Mr. Bickersteth, a case in which excision of the whole elbow-joint was performed immediately on admission. The injury was a compound comminuted fracture of the joint produced by being crushed between the buffers of two railway carriages. It is ten weeks since the operation; the wound is nearly healed, the relative position of the fore-arm with the humerus having been maintained at an angle most conducive to utility afterwards.

In the lateral operations on the bladder with a view to remove foreign body or stone, and the operations for applying ligatures on large arteries in popliteal and subclavian aneurism, I have merely to observe, that I have several times operated for aneurism including the subclavian, and for the removal of stone or foreign body from the bladder by the lateral operation, but *have no death to record*.

At this stage of the record, as probably the case may never appear in any other form, I may probably be excused stating that I have lately performed the lateral operation on the bladder in a youth of twenty, for the removal of a pen-case rather more than three inches and three quarters in length, and having a diameter equal to number eleven of Weiss's catheter gauge. He was taken into the Infirmary on the 28th of October last, in a state of great emaciation, having experienced much suffering from the presence of the pen-case in the bladder six months. In the last three weeks he had been much reduced by diarrhoea and night sweats, added to which, there was a slough on the back about the size of the palm of the hand: the pen-

case had been introduced into the urethra by himself, and had soon slipped beyond his reach.

The operation was performed on the 31st of October, and his survival was considered doubtful. Some difficulty was experienced in extracting the pen-case, as it was fixed transversely across the bladder, with its ends resting laterally. It was encrusted with a deposit of the triple phosphate, having an accumulation at either end, giving a sensation to the finger of a bulbous expansion. The application of the forceps unfortunately separated the pen-case from the deposit, the bulbous portions of which were so adherent to the surface of the bladder, as to require repeated efforts of the finger to effect their separation. The quantity removed was sufficient to have formed a good-sized stone. Up to Friday, Nov. 24th, he had not had one untoward symptom. The diarrhoea and night sweats ceased at once, without the aid of medicine; in fact, his treatment, with the exception of an occasional slight laxative, has been solely dietetic: the wound was nearly closed, and the bulk of the urine passing naturally: but on that day (Friday) he had an epileptic seizure, which recurred several times until the following Sunday. Since then (Nov. 26th) he has not had any return, and is now passing urine naturally; the wound on the back cicatrizing. In short, he is nearly well, the epilepsy not appearing to have produced any drawback.

In the operations for strangulated bowel, in femoral, inguinal, and scrotal hernia, the deaths were *one in four*. This I consider an unusual degree of mortality, and is by no means to be taken as a criterion of the value of the operation. It is easily explained. The cases of death, with one exception, were varying in age from 71 to 81, a period of life in which feebleness of constitution is most likely to interfere with the necessary reparative process; the exception was 50, with the intestine gangrenous. In some of the other cases the intestine was gangrened, and all had suffered from irreducible protrusion several days; of course, submitted to the administration of "irritating injections" and "drastic purgatives," subjected to repeated attempts at reduction by the taxis, and only brought to the Infirmary as a last resource; the sur-

geons in attendance either declining to operate, or the patients unwilling to submit.

Still, one death in four, however great I may deem the mortality, is less than the average recorded as occurring elsewhere. Mr. Phillips says, "In the hospitals in Paris it is estimated that half of the patients who are operated upon for hernia die; in London I believe the results to be little more favourable." My own experience leads me to believe the danger in hernia to be from delaying the operation. Mr. Phillips says, "I believe, in the present day, the operation for hernia has such unfavourable results because we wait too long, until, in fact, peritonitis is developed†." To this I cannot plead guilty. I have been obliged to operate on cases when they came to hand, however long the previous delay had been before they were brought to the Infirmary, and, as has been shewn, often under very untoward circumstances, where little hope was entertained of a favourable result; but in every case in which the opportunity was afforded of performing the operation early, the result was successful; and such is my experience of this operation, that were I the subject of strangulated hernia, I should prefer the operation at once, relying with perfect confidence on the result, to the risk attendant upon the delay and repeated attempts at reduction by the taxis.

Amputations, or removal of portions of bone, in the varied cases of compound fracture, with a view to save the limb.

Omitting all notice whatever of the cases of compound fracture which required only simple means to secure their favourable termination, and of those cases in which amputation of the limb was objected to by the patient, but which terminated unsuccessfully, the limbs being adjusted in the best manner the circumstances would admit of; this statement will only record those severe cases of compound fracture, in which amputation of the limb was not considered justifiable, but in which enlargement of the wound, and sawing off portions of the fractured fragments were deemed necessary either to the reduction or proper adjustment, by

* MED. GAZ. Oct. 9, 1840, p. 88.

† Ibid.

which a more safe and speedy cure might be accomplished. And here I find I cannot describe the varieties so perspicuously as I could wish, without deviating from my plan of not stating the number of operations. As, however, I think these, together with the class which is to follow, viz. the removal of tumors, do not come strictly under the denomination of capital operations, the deviation may not be thought material.

Of such cases I have to record, *thirty-five* of the leg, with *four* deaths.

Of the deaths, the first was a man aged 34, with compound fracture of the right leg, and simple fracture of the left thigh; he died on the fourth day, of effusion on the brain.

The second, a man aged 72, with compound fracture of the right thigh and left leg, occasioned by the fall of some balks of timber: he sank in sixteen days.

The third, a boy aged 12, with compound fracture of both legs, attended with great laceration of the soft parts, and comminution of the bones, occasioned by the passage of a railway carriage over them: he survived two days.

The fourth, a woman aged 72, with compound fracture of the leg, caused by falling into an open sewer: she died on the twenty-fifth day.

I have *four* cases of the thigh, of which *one* died. The case of death was a man aged 23, with compound fracture of the left thigh in the middle of the shaft, and a distinct compound comminuted fracture of the patella of the same limb, laying open the knee-joint, occasioned by a fall into a graving dock: he only lived two days.

One of the successful cases was so remarkable a one, that I shall not hesitate to introduce it here. A man, aged 40, with compound comminuted fracture of the patella, completely laying open the knee-joint: it was produced by the knee coming in contact with the tire of a carriage-wheel, while in the act of being run away with by a horse he was riding. The patella was so smashed, that its entire removal was advised; this was done, with as much of the capsular ligament as possible; the wound was dressed with strips of lint covered with carded cotton, and the limb maintained in the extended position for three months, at the expiration of which the wound had healed

without an untoward symptom. A fortnight afterwards he was discharged, provided with an instrument around the knee, so contrived with a spring as to preserve the limb extended, and yet admit of the flexor muscles bending the knee. I have seen him several times since walking in the town, and on one occasion without the instrument. When reproved for so doing, he explained it by saying the spring had broken: he was soon supplied with another, and I have now lost sight of him for a long time.

In this class I have included a successful operation for ununited simple fracture of the thigh. The operation of cutting down upon and turning out the ends of the fractured bone, proved a formidable one, and occupied a considerable time. He was discharged cured at the end of ten months, having previously, for more than three months, with the thigh secured in pasteboard splints, walked out on crutches in the Infirmary garden when the weather permitted.

I have *four* cases of the humerus, of which *one* died. The case of death was a man aged 35. The compound fracture was produced by a fall from a scaffold. He was carried off by an attack of erysipelas in the ninth week.

I have *seven* cases of the forearm and hand, of which *two* died. Of the deaths, one case, a man aged 58, with compound fracture of the radius, died at the end of eight weeks, exhausted with phlegmonous erysipelas, and sloughing of the back. The other, a man aged 34, with compound fracture of the radius near the wrist, occasioned by a fall from a cart while in a state of intoxication, was seized with tetanus on the seventh day, and died on the ninth.

Lastly, the removal of tumors. Of these operations I have had *twenty-five*, with *four* deaths. The operations include removal of scirrhus, osteo-sarcomatous and carcinomatous tumors from various parts of the body, as the face, head, neck, breast, back, loins, and thigh.

These results, when compared with the statistical reports already published, naturally lead one to inquire, how comes this great disparity in favour of the Liverpool Infirmary? And those persons acquainted with the localities will ask, can it be attributable to the

hospital, its situation, cleanliness, or ventilation?

As to its situation.—It is well known that the Liverpool Infirmary occupies a site which may be considered one of the most elevated in the town; the situation being open, the district, comparatively speaking, thinly populated, and the majority of the houses in the vicinity standing on a lower level than the building.

As to its cleanliness.—It has been the remark of visitors, that it is most clean; and some gentlemen on the management, who had expressly visited other hospitals, when an inquiry was instituted as to its ventilation, declared that no hospital they had seen was at all to compare with it in cleanliness.

As to its ventilation.—Such is the anxiety and watchfulness to keep the wards sweet, that it frequently interferes with the feelings of the patients, who are a class generally accustomed to close and ill-ventilated dwellings.

Again: has the locality of Liverpool any influence in contributing to this success? I believe an impression is now current very unfavourable to the salubrity of this neighbourhood, entirely from an erroneous view having been taken of a pamphlet, *On the Physical Causes of the high rate of Mortality in Liverpool*, by Dr. Duncan; a more appropriate title for which would have been, on the physical causes of the high rate of mortality in *particular districts* of Liverpool; for this is all that has been proved. He certainly has not refuted the “prevalent impression,” which led Dr. Dobson, one of the physicians to the infirmary, a building at that period situated at the top of Shawsbrow, then one of the most elevated and open parts of the town, and but thinly populated—such was at that time the wisdom and care manifested by the founders in the selection of a site, and equally displayed by their successors in the choice of the situation of the present infirmary—to write in 1774, “Liverpool is one of the healthiest places in the kingdom in proportion to the number of the inhabitants; or Mr. Moss, in his *Medical Survey of Liverpool*, published ten years later, to say, “the air is much more pure than is commonly found in many parts of the kingdom.” “Liverpool may truly be said to be a healthful town, and that much more so than

the generality of towns in the kingdom in proportion to their amplitudes.” But since then, a Liverpool medical journal, in 1834, has spoken of “the general character of the town for healthiness;” and, as Dr. Duncan says, “various good geological reasons were assigned to account for it.” And I question very much whether the complaints made against him, as he says, by “the public authorities” here were not just, when “they stigmatised some evidence given by him before a committee of the House of Commons on the health of towns, on the high rate of mortality in Liverpool, as a foul and unmerited libel on the good old town.”

His evidence ought to have been confined to the high rate of mortality in *particular districts* of Liverpool, not of the town in general; for on that it will not bear, as is proved not only by his own tables, but I think my results of operations; and the comparisons which follow may be fairly taken in as an additional criterion of the value of such generalising.

Compare his own expressions when drawing a contrast of the wards of the town. He says, “not the least striking result of the investigation is the very different rate of mortality which we have found going on in the various districts of the town; for while in Rodney Street and Abercromby Wards,” (in the elevated part of which the Infirmary is situated) “with upwards of 30,000 inhabitants, the mortality is below that of Birmingham, the most favoured in this respect of the large towns of England; in Vauxhall ward, with a nearly equal amount of population, the mortality exceeds that which prevails in tropical regions†.”

This may be considered the *most* striking result of the investigation, and is not a little confirmed by what follows. He says, “does any one suppose that if the inhabitants of Rodney Street and Abercromby Square were to exchange places with those of Vauxhall or Exchange wards, leaving their spacious mansions to be occupied by the inhabitants of the latter district, while they took up their residence in the filthy and miserable courts and cellars of Vauxhall or Exchange—their relative command of the necessities of life remaining undisturbed—does any one

* Dr. Duncan's Pamphlet, page 7.

† Ibid. p. 60.

suppose that the relative mortality of the two classes would likewise remain unaltered? that 1 in 23 would still die in Rodney Street, and not more than 1 in 41 in Vauxhall? or that the average duration of life would not be prolonged beyond 15 years among the former inhabitants of Vauxhall, and fall far below 35 years among the present occupants of Rodney Street?"*

Does this refute the statements of Dr. Dobson, Mr. Moss, and the Liverpool Medical Journal, as quoted by himself at the seventh page, and which he sets off with, resolved to overturn? Does it not rather confirm, not only the printed records of the health of the town, but the justness of the "prevalent impression" of the salubrity of the neighbourhood?

It happens, however, that there is now a fancy abroad against the health of the town, entirely owing to Dr. Duncan's pamphlet, which I trust the close and consistent reasoning of thinking men may yet dispel. I think great credit is due to him for having drawn attention to the abominations of some districts of the town, with a view to their removal, but that the conclusions which are drawn with respect to the general healthiness of the town are borne out even by his own tables, I must object.

Does it speak much for the acumen of the Liverpool Literary and Philosophical Society, who have published the pamphlet? Ought they not to have been the guardians of the character and interests of Liverpool, and not have been the means of circulating what has operated unjustly to the disadvantage of the town?

In my thirty years' knowledge of Liverpool, I can safely say the natives with whom I have been acquainted, or who have come under my observation as prominent persons in the town, attain a good old age. I have at this moment in view one gentleman whom I occasionally meet, who is nearly 90. Another upwards of eighty, who is more active than many persons at half his age. But that the general healthiness of Liverpool is to be denounced because the general bill of mortality is swollen with the deaths of such sick poor as come here with already impaired constitutions and inherent maladies, to

be developed by a residence in the particular districts described, is most unfair.

That this great mortality in particular districts is a monster evil, demanding the prompt interference of the local authorities, no one can doubt. Let the Corporation set the example. They are trustees for the public good; let them prove themselves conservators of the public health. They have already expended thousands upon thousands in contesting their right to the conservancy of the river; let them apply an equal zeal and energy to the conservancy of the health of the town, and let not the plea of a want of funds stop the good undertaking.

The conclusion at which I arrive after a perusal of the tables is, that we are not to infer that the locality of Liverpool is unhealthy; but that the atmosphere in particular districts of the town is very much deteriorated by the construction of the dwellings, the close manner in which the inmates are packed, "in some instances *thirty* human beings sleeping in a space furnished with a supply of air sufficient for the wants of only *seven*, and each inhaling the poison which his neighbour generates*;" and the filthy habits of the population, they being chiefly low Irish, "as well as vagrants and vagabonds of all descriptions†."

That these should produce their usual results of fever and death is not to be wondered at; the surprise would be did they not; but I believe such a combination of ill ventilated dwellings, crowded population, and filthy habits, would produce these results in any locality. And, that the state of atmosphere generated from such sources does operate to the disadvantage of those particular districts of the town, is pretty clearly manifest, if we contrast the published results of amputations performed on cases in a small hospital, containing about fifty surgical beds, at the north part of the town, with what I have laid before the profession.‡

Before entering on the comparison, I must state, that I cannot acquiesce in the feeling which dictated to Mr. Phillips a determination to withhold the names of several hospitals included in the returns made to him, because "in

* Dr. Duncan's Pamphlet, p. 18.

† Ibid.

‡ MEDICAL GAZETTE, May 7, 1841, p. 269.

certain hospitals the mortality after amputation had exceeded fifty three per cent. in several not exceeded twelve per cent and in one of the number, out of twenty amputations there being only one fatal result.*

What! in the face of such frightful mortality as is represented, a mortality so annihilating as almost to raise a question as to the value of operations at all, are we to exercise any reserve?

INFIRMARY.

Amputations above the knee, one death in eleven.

Below the knee, one death in six.

As I have no death after amputation of the fore-arm, I cannot follow out the comparison otherwise than by combining the amputations above and below the elbow, thus:—

Of the arm, one death in eighteen.

To satisfy the reader my inference is fair, that the Infirmary has been the sufferer by my classing my results in its name, I will quote from its eighty-seventh printed annual report, in which there is a brief statement of operations during two years, the only general record which can be got at, which I greatly lament, for I am satisfied, and it is no "vague impression," could a general record be obtained for the period of nearly eighteen years I have been associated with it as surgeon, a still more favourable result could be shewn.

"Amputations of upper extremities, including one of the shoulder-joint 20, of which 1 died.
Amputations of lower extremities, three individuals lost two legs each 23, of which 2 died||."

43 3

So that there were only 3 deaths in 43 amputations. One in $14\frac{1}{3}$.

Whereas, if we take the published report of the Northern Hospital for seven years, what do we learn—

"Amputations of upper extremities . . . 16, of which 5 died.
Amputations of lower extremities . . . 57, of which 15 died.

73 20||."

And that there were 20 deaths in 73 amputations, or one in $3\frac{1}{2}$.

Those are startling comparisons! and for which I was wholly unprepared. It is only within a few days that my attention has been called to the statement of the Northern Hospital, or I should have felt bound to draw the contrast sooner, rather than quietly have allowed an impression, so unfavourable to Liverpool operative surgery, to pass uncontradicted. I conclude it to be correct, as it bears the impress of authority, the communication to the Editor of the London MEDICAL GAZETTE, having the signature Edward Parker, M.R.C.S.E. as-

I think this delicacy has lessened the value of his deductions, and he has rejected a most valuable clue to the causes of such mortality. This, however, must become a most important part of the inquiry.

The results of the comparison will be as follow; and as my chief field of operation has been the Infirmary, I shall class my results in its name, though I believe it will suffer by it.

NORTHERN HOSPITAL.

Amputations above the knee, one death in five. Deaths more than double†.

Below the knee, one in less than $3\frac{1}{2}$. Deaths nearly double‡.

Of the arm, about one in $3\frac{1}{4}$. Deaths more than five times greater§.

sistant house-surgeon to the hospital. How far he has been warranted in forming such a general conclusion as his first, viz. "that amputation is a more dangerous operation than is generally supposed, the proportion of fatal cases being one in $3\frac{1}{2}$," I leave the profession to judge.

But to resume the comparison.

Located on the margin of the canal basins, near what was the bank of the river, called the north shore, but now a dock, not much above the level of high water-mark, in one of the most densely crowded districts of the town,

* MEDICAL GAZETTE, June 9, 1838, p. 459.

† MEDICAL GAZETTE, May 7, 1841, p. 279.

‡ *Ib.*

§ *Ib.*

|| 87th Printed Report of the Liverpool Infirmary for the year from January 1835, to January 1836.

* MEDICAL GAZETTE, May 7, 1841, p. 270.

itself constructed out of two private dwellings, the Northern Hospital is almost surrounded by lofty warehouses.

In comparing these results, is it irrational to infer that the situation of the hospitals has had something to do with the diversity of success?

Entering a little more closely into the comparison, what is the picture?

The Infirmary is situated in "Abercromby Ward, where fever prevails the *least*, only 1 in 237 of the inhabitants having been attended by the dispensaries, and where there is also the *smallest* proportion of the population, between one-fourth and one fifth-resident in courts and cellars; where the proportion of deaths from *all* causes is 1 to 41½, a mortality *below* that of Birmingham, the *most favoured* in this respect of the large towns of England*."

The Northern Hospital is situated in Vauxhall ward, "the *worst* in point of mortality, the deaths amounting to 1 in 23½, the mortality *exceeding* that which prevails in tropical regions; where the *largest* proportion, more than one half, of the population reside in courts or cellars, with the most defective sewerage, and in which fever is *most* prevalent, 1 in 27 of the inhabitants having been annually attended by the dispensaries alone.†"

The comparison being complete, I may perhaps be excused entering briefly into the history of the Northern Hospital. It was established upon what, to a superficial observer, appeared a very humane argument, viz. that the distance from the docks to the Infirmary being about a mile, the accidents occurring in that locality suffered so much from delay in the removal, that it was desirable to bring a hospital to them: this was done by the conversion of a private dwelling, to which in course of time another was added. But the promoters of this humane project forgot their principle in their election of surgeons: three were appointed, whose private residences equalled, if they did not exceed in distance, that which had been condemned as prejudicial. Of course the severe accidents requiring amputation, and other treatment which the surgeons only could execute, had to wait until they were obtained, and after that delay, had in the struggle for

recovery (under the best circumstances difficult) to contend with all the disadvantages of the locality, the result of which, as published by the assistant-house surgeon, is sufficiently manifest.

This is a subject which must ere long force itself upon the attention of all founders and governors of hospitals, and demand their serious consideration; it seems generally to have been overlooked, and a really humane anxiety to embrace every advantage which could possibly contribute to render hospitals what they profess to be, to have been set aside by an eagerness to follow out particular views, or forward individual interests. Certainly, the published statement of results of amputations at the Northern Hospital has furnished the strongest argument that could have been adduced against the establishment of a hospital in such a locality.

To the clear unprejudiced judgment of the truly benevolent, the remedy is obvious; but to those whose philanthropy may be alloyed by inferior considerations, it would be vain to suggest it.

SOME OBSERVATIONS

ON

EXANTHEMATOUS, OR SCARLATINAL DROPSY.

BY JOHN THOMAS NICHOLSON LIPSCOMB,

Member of the Royal College of Surgeons.

(For the Medical Gazette.)

THE importance of that form of dropsy which succeeds to scarlatina, has been variously estimated by different authors. Morton, the first English physician who gave an account of it, evidently regarded it as a disease of no slight importance; and Pleniz, who wrote a description of the scarlatina, as it prevailed epidemically at Vienna, in the middle of the eighteenth century, speaks of it as more dangerous than the primary fever; whilst Cullen, Armstrong, Lewins, and others, make but a bare mention of it in their works; and Sydenham, that excellent physician and accurate observer, does not even allude to it. It has, however, since Dr. Bright has made known to us the connection existing between albuminous urine and structural disease of the kidney, claimed a greater share of the

* Dr. Duncan's Pamphlet, p. 45.

† Ibid.

attention of the profession ; and its true pathological condition begins now to be better understood.

It was considered by Dr. Withering to succeed chiefly to the malignant species of scarlet fever ; though he admits, with Dr. Percival, that it is occasionally to be met with after its more mild forms : later observations, however, have shown that dropsical effusion is most frequent when the primary fever has been trivial ; not so much, perhaps, because the primary fever was slight, but because, being slight, it attracted but little attention ; and hence the patient had not that care to avoid exposure to cold, that would have been given had the disease been more severe.

Neither sex nor age are exempt from it, though it is much less frequent in advanced than early life ; probably from the greater delicacy and susceptibility of the skin during childhood, and the greater frequency of scarlatina at that time. It generally commences its attack at a period varying from one to two or three weeks after the decline of the fever, though occasionally not till later. A case is on record in which five weeks intervened ; and Dr. Gull, of Guy's Hospital, met with one in which the patient did not apply to him until a year after the attack ; the dropsy, if there had been any, not attracting attention until that time. It is preceded for the most part by peevishness, general languor and debility, restlessness, dyspnœa, a leuco-phlegmatic countenance, the face sometimes flushed, skin hot and dry, nausea, vomiting, loss of appetite, a white furred tongue, constipated bowels, scanty turbid and high coloured urine, somewhat bloody in appearance, and accompanied with a lateritious deposit ; after which the face and upper extremities begin to swell, and anasarca makes its appearance, generally in the face first, though I have in some instances detected it in the fore-part of the legs when it was not observable in any other parts of the body*. From the face it gradually extends to the extremities, abdomen, and scrotum. The pulse is quick, weak, and jerking ; there is distressing vomiting, disturbed sleep, and great cerebral excitement, accompanied with convulsions. Not unfrequently, if the

disease be allowed to continue its course unchecked, effusion rapidly takes place into the great serous cavities, when the symptoms of either hydrocephalus or ascites manifest themselves ; and if not relieved, speedily prove fatal. From the commencement of the dropsy, albumen may, in almost every case, be detected in the urine, by gently applying heat to it in a glass test tube. Nitric acid should always be added, to distinguish albumen from the earthy phosphates ; and here I would recommend, that in all cases of recovery from scarlet fever, the urine be frequently and accurately tested, that the slightest trace of albumen may be detected as early as it occurs.

However true Sydenham's remark, "*æger non raro multâ aliâ de causâ, quam nimîâ medici diligentîâ ad plures migrat,*" may be with respect to scarlatina, it is certainly not applicable to the disease now under consideration, for though I believe that if attention be early drawn to the condition of the patient this disease will seldom prove fatal ; that warm clothing with flannel worn next the skin, the avoiding the least degree of cold and damp, together with the daily exhibition of a brisk purgative, and a moderate non-stimulating diet, will frequently be found sufficient to effect a cure ; yet, if the disease have advanced beyond this, the first stage, if the anasarca be general and considerable, and if the urine deposit a large quantity of albumen on the application of heat, a more strict restraint will be absolutely necessary : the patient should be confined to his bed ; the room be kept warm, and of equable temperature ; and diaphoretics, such as the *Liq. Ammon. Acet.*, *ipeacuanha* and antimony wines, be administered in combination with the *Tinct. Digitalis* every four or five hours ; and a purgative, say the compound jalap powder, which I regard as one of the best, be given every morning. The exhibition, too, of a warm bath every, or every other night, will materially tend to produce diaphoresis. Should, however, these means fail, should the pulse be

* Drs. Abercromby and Blackall each mention a case in which the urine was not albuminous ; but all those that I have had opportunity of investigating have contained serum.

† Dr. Blackall says digitalis is the sovereign remedy : I know of no instance where it has failed when properly exhibited.

* Dr. Blackall, of Exeter, bears testimony to the same fact.

quick, hard, and incompressible, and the patient complain of pain in the loins, it will be found desirable to deplete locally, by the application of a cupping glass or leeches over the loins; or in some cases, particularly if there be much difficulty of breathing, to abstract blood from the arm; regard of course being paid to the age and strength of the patient*. Mercury should only be given to aid the action of cathartics.

In the above remarks, it will be observed, I have made no special allusion to the employment of diuretics. Those of a stimulating character I regard as decidedly prejudicial; but the more cool and attenuating, and those which diminish inflammatory action, *e. g.* neutral salts and digitalis, may often be of advantage, though, when the urine contains serum, I give the preference to those medicines which determine to the skin, rather than run the risk of over stimulating an organ which is already in a state at least of congestion from increased action. I am, however, aware it may be urged that diuretics do not increase the quantity of albumen present.

The following cases, which have all occurred to me during the late autumn, when scarlatina and its sequelæ were both prevalent and fatal in this neighbourhood, may perhaps serve to elucidate the preceding observations. Case the first shows that albumen may occasionally be detected in the urine after scarlatina, before œdema of the body is observable; and that the disease, when once apparently removed, if not entirely eradicated, is liable to relapse.

Case the third, the only one that fell under my observation in which the patient died, gave me an opportunity of examining the pathological conditions of the different organs, which I have briefly reported.

In case the fifth it is worthy of remark, how rapidly the water disappeared after the child had accidentally vomited. This result, which has been observed by others, has induced them to recommend the employment of emetics in similar cases. The blue powder, prescribed on the 1st October, was administered with the view of im-

proving the character of the alvine evacuations, and was not intended to act upon the general system.

In case the sixth, I could not detect any anarsaca: possibly effusion had dot taken place, and was prevented by early treatment.

CASE I.—F. H. æt. 5, had scarlatina in 1843; soon afterwards the urine became slightly coagulable by heat; for which he took a compound jalap powder every morning. In a few days the albumen was removed, and the urine became healthy; he then ceased taking medicine. After the lapse of a few more days, I again submitted his urine to the application of heat; and found that it again deposited albumen. I could now, for the first time, by careful examination, detect a slight pitting on the lower extremities; he was treated with the Liq. Ammon. Acet., antimony, and ipecacuanha wines three times a day, and a compound jalap powder every morning. In the course of two more days, the urine was once more free from albumen. The boy continued well.

CASE II.—M. C. æt. 8, on the 20th August last, was seized with the ordinary precursory symptoms of scarlet fever, and on the next or following day the rash made its appearance, and ran through a very irregular course, disappearing, and again reappearing, accompanied with considerable cerebral excitement; for which local depletion, by means of leeches, was had recourse to on two different occasions. On the 5th September the face and legs became œdematous; the urine was scanty and pale, depositing a small sediment on the application of heat.

To take a small dose of blue pill at bedtime, and comp. jalap powder each following morning. Flannel to be worn next the skin.

After this the legs continued œdematous; and the urine deposited the same quantity of albumen on the application of heat. A mixture of Liq. Ammon. Acet. antimony and ipecacuanha wines, was prescribed with fifteen grains of comp. jalap powder every morning; from which time the patient gradually recovered, and on 10th inst. the urine remained unchanged on the application of heat.

This patient complained of no pain or uneasiness from the succession of the dropsy; slight pitting of the lower

* Dr. Lewins, of Haddington, thinks that bleeding ought always to be had recourse to when the mild remedies recommended by Dr. Cullen fail.

extremities, and albuminous urine, were the only bad symptoms.

CASE III.—G. S. æt. 4, on the 7th August, 1843, complained of headache, sore throat, &c. On the 9th the body was covered with a scarlet rash, which disappeared on the 15th. Some days afterwards, near upon a fortnight, the child had thirst; heat of skin; headache; palpitation; restlessness; dyspnoea; the bowels were open; stools of a pale colour; urine scanty and high coloured, or rather having a dull leaden hue; great inclination to the horizontal posture, and the left side; dyspnoea increased by lying down; almost constant nausea, accompanied with occasional vomiting.

The above symptoms were elicited from the mother, who requested me on the afternoon of the 5th September to see him. I found him almost moribund: there was general anasarca; an enlarged abdomen; distressing dyspnoea; great sickness, and he was totally unable to take anything; urine was strongly coagulable by heat and nitric acid. The child died at 10 P.M.

Autopsy 35 hours after death.—The whole body was very œdematous; there were large quantities of serum in the cavities of the chest and abdomen; no flocculi floating in it. The lungs were healthy; heart perhaps somewhat pale, otherwise healthy; peritoneal coat of liver opaque; spleen natural. The kidneys indicated an early stage of Bright's disease: they were large, weighing $3\frac{1}{2}$ oz. each, much congested; the cortical layer thickened, and projecting into the substance of the organ, between and greatly compressing the tubuli miniferi. Upon removing the fibrous coat, the surface was mottled as though from the deposition of lymph.

The head was not examined.

CASE IV.—R. P. æt. 11, was seized, on the 20th August, 1843, with pyrexia, sore throat, headache, &c. which were followed by a scarlet eruption over the whole body. She was not, however, sufficiently ill to lie by, or apply for medical relief; about a week afterwards, she complained of a degree of languor; her face appeared puffy, the abdomen became large, and her legs swelled, particularly towards night. On the 7th September I was applied to, and found her, although not entirely free from constitutional symptoms, yet suffering but little from

them; there was no pain; the urine was scanty, of a deep red colour, and moderately coagulable by heat. I prescribed calomel and compound antimony powder every night, and a compound jalap powder each following morning. Under this treatment she did not seem to improve: the œdema was not at all diminished.

Ordered to be clothed in flannel, and to be kept in a warm apartment.

R. Liq. Ammon. Acet. ζ ij.; Vini. Ant. P. Tart. Vini. Ipecacuanhæ, aa. ζ iss.; Syrup Aurant. ζ ij.; Aquæ. Destill. ζ iiiss. M. cap. cochl. i. magn. ter quotidie.

In a day or two she began to mend; the quantity of albumen present in the urine gradually decreased, and on the 21st inst. she was considered convalescent.

CASE V.—Thomas —, æt. 7, was attacked with sore-throat, headache, &c. on the 1st September: on the following day an eruption of a bright scarlet colour made its appearance. No medical attendance. On the 7th September, when I first saw him, the exanthematous rash had disappeared. Face was somewhat puffy, abdomen enlarged, and there was slight pitting down the fore part of the legs. Urine natural as to quantity, but pale and turbid. Upon examining it with heat I could detect a very minute trace only of albumen.

R. Hydr. Chloridi, gr. iss.; Pulv. Jalapæ co. gr. ij. ft. Pulv. om. nocte; Pulv. Jalapæ co. gr. xx. om. mane.

After continuing this for a few days the œdema became diminished, so that the pitting on the legs was scarcely perceptible; but in consequence of exposure to cold he relapsed, and on the 16th inst. the swelling over the whole body was much increased.

To be clothed in flannel, and to take a mixture of the Liq. Ammon. Acet. Antimony and Ipecacuanha wines, three times a day, and a Comp. Jalap Powder every morning.

On the 19th, the œdema was so much increased that the eyes were nearly closed, and he was totally unable to button his clothes. The urine, which before deposited but little sediment on the application of heat, is now moderately coagulable.

Continue the same medicines in increased doses, and administer a warm bath every night.

From this time the patient improved

until the 23d inst. when he complained of pain across the loins. The skin was hot and dry; the pulse full, hard, and frequent; cough and dyspnœa.

Sanguis detrahatur à Brachio ad ʒij.;
Rep. Medicamenta.

On the following day the swelling was still further increased, the scrotum being enormously distended. The blood evinced neither a buffed nor cupped appearance, but was florid, and had a full share of crassamentum. The last medicines produced nausea.

Rep. Medicamenta.

The scrotum was scarified, and a very large quantity of serum gradually oozed out.

25th.—All the symptoms augmented; extremities cold; pulse quick and intermitting. Ascites and general hydrothorax to a considerable extent. Child can only keep the semi-erect posture, on account of the urgency of dyspnœa. Bowels not freely acted upon; last few motions were dark coloured.

Ordered heated bran to the extremities, a powder of calomel and antimony directly, and an aperient an hour after.

After this the child vomited, when the ascites and part of the anasarca suddenly disappeared, and the scrotum returned to its natural size.

27th.—Nausea still continues.

An aperient powder to be taken directly, and an effervescing saline draught with ℥viij. Tinct. digitalis every three or four hours.

Oct. 1.—Gradual improvement has taken place since last report. The nausea, which was entirely removed by the effervescing medicine, has again returned, accompanied with a disinclination for food, and vomiting, principally mucus tinged with blood, on taking any thing into the stomach; urine turbid, and very deep coloured, of a bloody appearance, still albuminous, though much less so than before. Pulse feeble; bowels somewhat costive; motions offensive; tongue furred.

R Magn. Carb. ʒss.; Acidi Hydrocyan. Mij.; Aq. Cinnam. ʒvj.; Aq. Destillat. ʒii. ʒii. M. Cap. Cochl. i. Magn. ter quotidie.

R Hydr. c. Cretâ; Sodæ Sesq. Carb.; Pulv. Rhei. aa. ʒij. M. ft. Pulv. ter in die sumend. ex avenâ. To be continued for two days.

4th.—Vomiting ceased after taking

the first dose of the acid. Child not so well to-day, from having taken cold; the dyspnœa is more urgent, and accompanied with a short hacking cough. He is now, and has been for many hours, in a profuse perspiration.

R Potass. Nitrat. ʒij.; Pulv. Trag. co. ʒss.; Vin. Ipecac. ʒij.; Aq. Cinnam. ʒiv.; Aq. Destillat. ʒiiss. M. Cap. Cochl. i. magna quartâ q. q. horâ.

16th.—Convalescent.

CASE VI.—T. N. æt. 4, was attacked with scarlatina in the middle of August last, which ran its course very irregularly, the eruption making its appearance, and soon disappearing. The brain, too, was much affected. On the 15th Sept. upon examining the urine, I for the first time detected the presence of albumen. Flannel next the skin was prescribed, and the child took the ordinary mixture of Liq. Ammon. Acet. Antimony and Ipecacuanha wines, three times in the day, and a compound jalap powder every morning. This treatment was persevered in till the 20th inst. when the urine was again examined, and remained unchanged upon the application of heat.

St. Albans, Dec. 4, 1843.

A CASE OF UNUSUAL DISLOCATION OF THE HIP,

REDUCED BY A NEW (?) METHOD; WITH
REMARKS.

By JOHN DAVIES, M.D.

Surgeon to the General Infirmary at Hertford,
&c. &c. &c.

(For the Medical Gazette.)

JOHN HART, aged 20 years, of middling habit of body, was admitted at the General Infirmary, under my care, on the 14th November ult., with a dislocation of the head of the left femur into the obturator foramen. The accident had occurred on the 12th, two days previous to his admission. Considerable force had been used by the medical man who had been first called to the case, and, according to the patient's account, a large quantity of blood had been abstracted; but he could not succeed in reducing the bone.

After the patient's admission into the infirmary, the usual method of reduction was put in execution, namely, that of using extension on the dislocated limb across the opposite one, and of an

attempt to elevate the head of the bone from its false position; but this plan did not succeed, although persevered in for a long time with considerable force. The other mode, recommended by Sir A. Cooper for dislocation into the foramen ovale of three or four weeks' standing, was then adopted. The patient was placed on his back, and his pelvis fixed by a round towel to the bedstead. A padded strap was then placed round the upper part of the dislocated limb: to this strap the pullies were attached, so as to direct the force outwards, at a right angle with the body. This plan caused the removal of the head of the bone from the obturator foramen in the course of two or three minutes, and its reduction into the acetabulum took place with a loud "snap." It was supposed at the time that the head of the bone was left in the socket, but I have a strong suspicion that it passed over at the same moment to the ischiatic notch. Sir A. Cooper, in his work on Dislocations and Fractures, speaking of the reduction of the head of the bone from the foramen ovale, according to the plan just described, says, that "great care must be taken not to advance the leg in any considerable degree, otherwise the head of the thigh-bone will be forced behind the acetabulum into the ischiatic notch, *from whence it cannot be afterwards reduced.*" I feel pretty certain that I did not let go the lever at the moment the head of the bone "snapped" into the socket, and that, consequently, it was thrown out again, over the outer rim of the acetabulum, into another false position.

On examining the hip minutely on the 24th of the same month, the swelling having in a great measure subsided, I discovered that all was not right. The great trochanter was farther back, and rather lower, than it ought to be when in its natural position: the toes turned a little inwards, and the knee was nearly an inch lower than the opposite one. In fact, I discovered that the head of the femur was situated in the lesser sacro-ischiatic notch, resting immediately under the spine of the ischium.

The usual course of extension recommended for dislocation into the ischiatic notch was adopted. The patient was placed on his right (sound)

side, with his pelvis fixed by a padded strap passing between the pudendum and the dislocated limb, and fastened to the bedstead. The pullies were attached to another strap, buckled round the limb immediately above the knee, and extension was made across the opposite thigh, nearly at a right angle with the body, while an attempt was made with great force to elevate the head of the femur from its mal-position. These efforts were persevered in for a considerable time, but without the slightest appearance of success.

Taking into consideration the nature of the case, with the relative positions of the parts concerned, I was induced to adopt the following method. The patient was placed on his right side—the sound side: a broad towel was applied round his pelvis, so as to fix it firmly to the bedstead: a padded strap was placed round the dislocated limb, as high as possible; to this strap one end of the pullies was hooked, and the other end was fixed at some distance in front of the patient, so as to apply the force on the upper part of the thigh, forward, at a right angle with the body. Whilst the pullies were acting, an assistant had hold of the lower part of the limb, so as to use it as a lever, by gradually and gently pulling it backward, and rotating it slightly outward. At the same time I pushed the great trochanter forward. In about one minute the head of the bone was reduced into its socket.

The force required to move the head of the bone from its mal-position, by this plan, appeared very slight; for the pullies had scarcely commenced to act when I could distinctly feel it glide gently forward towards the acetabulum, into which it entered with great apparent ease, without any "snap" or noise.

The patient has been doing very well since, and is now going about upon crutches. He can move the limb very well.

The great, of all great authorities, Sir Astley Cooper, says, "I have seen no instance of a dislocation (of the hip) downwards and backwards. . . . I may be allowed to observe, that, if such a case ever does occur, it must be extremely rare."

There can be no doubt about the nature of the dislocation in this case, that it was backwards and downwards

to some extent: in fact, it was a dislocation of the head of the femur into the lesser ischiatic notch. But, on the other hand, there is, in my opinion, as little doubt that it was not the result of accident, but was caused by the action of the pullies, in reducing the previous dislocation from the foramen ovale. It may be a question whether any kind of casual injury—a blow or fall—can throw the head of the bone into the position in which it was placed in this case.

We might infer, from Sir A. Cooper's remark, that it is not unusual for the head of the bone to slip over the acetabulum into the ischiatic notch, in the attempt to reduce dislocation from the foramen obturatorium, according to the method adopted in the present case; for, he says, as already quoted, "great care must be taken not to advance the leg in any considerable degree, otherwise the head of the thigh-bone will be forced behind the acetabulum, into the ischiatic notch;" and, he adds, "from whence it cannot be afterwards reduced."

Now, as Sir Astley says that he, in all his extensive practice, had never seen a case of dislocation backwards and downwards, the above remarks must apply to dislocation into the upper or greater ischiatic notch. Yet one might suppose, from an examination of the skeleton, considering the relative situations of the foramen ovale, the acetabulum, and the upper and lower ischiatic foramina, that the last named is the one most likely to receive the head of the bone, if it should be drawn across the acetabulum by a force applied for the reduction of dislocation into the obturator hole, as used in this case, and as recommended by Sir Astley himself in cases of dislocation of long standing. It is evident that Sir A. Cooper did not intend that his expression should be taken according to the strict interpretation of its terms, when he remarks respecting the head of the bone slipping into the "ischiatic notch, from whence it cannot be afterwards reduced;" because no one knew better than he that cases of dislocation into that position had been reduced. His object in that expression is to caution surgeons against transferring the head of the bone into the ischiatic notch on its removal from the foramen ovale, by

impressing upon them the difficulty not the impossibility, of reducing it from that situation into its natural bed.

Having succeeded with such facility in bringing the head of the bone forward into the acetabulum by the plan adopted in the present case, it may be inferred that the same method would prove successful in similar cases. In the heading of this article I introduce the mark of interrogation after the word "new." It is very possible that my more learned brethren may be able to quote cases treated in a similar manner; but I can find no mention of such either in systematic works on surgery, or in those specially applying to dislocations.

The reason appears tolerably clear why the usual method adopted for the reduction of dislocation of the head of the femur into the ischiatic notch is attended with so much difficulty. Most of the force used in the extension of the limb, as well as that applied to the elevation of the upper part of the bone, is lost. The force produced by the pullies is counterbalanced by the resistance caused by the fascia, or strap which is used for fixing the pelvis. With the exception of the weight of the patient's body, the amount of the one force is pretty nearly equal to that of the other; for the band applied between the pudendum and the dislocated limb does not act directly upon the pelvis, but upon the upper part of the thigh, through the medium of the muscles; and when we consider the position and attachments of these muscles, we may well understand how the resistance of the strap must nearly counterbalance the force of the pullies.

The resistance of the strap, also, will almost bid defiance to any effort to lift the head of the bone from the ischiatic notch; for it tends to pull the upper part of the limb outward, whereas the course in which it ought to move, in order to get into the acetabulum, ought to be inward.

I may remark, likewise, in conclusion, that in dislocation into the foramen ovale, a similar objection applies to the usual mode of reduction. The strap or band which fixes the pelvis acts more and more powerfully in pressing the head of the bone, so as to retain it in the obturator hole the more the force of the pullies is made to in-

crease; whereas by using the strap as a fulcrum, as near the head of the bone as it can be applied, and by acting on the lower part of the limb as a lever, a reduction will probably be easily accomplished, if of recent date.

Hertford, Dec. 8, 1843.

DIAGNOSIS OF FRACTURES OF THE LOWER END OF THE RADIUS.

To the Editor of the Medical Gazette.

SIR,

THERE are one or two points connected with fractures of the lower end of the radius, which, I think, deserve more attention than has hitherto been paid to them, as diagnostic symptoms of this particular kind of injury: I refer to the prominent ulna, and peculiar displacement of the hand, which is met with in these cases.

When the radius is fractured within its lower inch, or inch and a half, by a fall on the hand, it will be found that, in the majority of cases, the following deformity exists:—The whole hand appears to be displaced laterally outwards, or in a state of abduction; that is to say, the ulnar edge of it, instead of being in a line with the ulna itself, occupies a position more external, or towards the radius, which causes the end of the ulna to project, and to be apparently dislocated. There is also generally found to be a depression on the opposite side, in the radius itself, in the situation of the fracture; and there is not unfrequently a prominence posteriorly above the carpus, when the displacement has taken place in this direction as well. The crepitus is not often present in these cases, for the fractured surfaces are so tightly locked together, that motion between them is seldom obtained.

The explanation of the above position of the hand no doubt is the following. When a person falls on the hand with sufficient violence to fracture the radius, the force, after it has produced the fracture, tells upon the lower portion of bone, and pushes it inwards towards the ulna, at the same time that it must take the wrist and hand with it, owing to its mode of connection with the carpus. The ulnar edge of the hand then loses its normal position with the ulna, causing the end of this bone

to stand out in so prominent and decided a manner. It is to these two latter symptoms that I attach so much importance, as being diagnostic of this particular kind of fracture; for I believe that in every case of injury about the wrist, from a fall upon the hand (whether in old or young people, though more frequently in the former), where there are found to be *this peculiar prominence of the ulna, and lateral displacement of the hand*, it may safely be said, that the lower end of the radius has been fractured, without the necessity of taking any other symptoms to help the diagnosis, even if no deformity is to be felt about the radius itself, or other part of the joint. I have come to the above conclusion after close observation and much attention to the subject, and believe them to be *sure diagnostic symptoms* of fracture of the lower end of the radius.

I have referred to this point in my work on Fractures, since which I have seen so many cases confirmatory of it, that I am induced to trouble you with these few remarks, in the hope that you may think them important enough to occupy a space in your valuable journal.—I remain, sir,

Your obedient servant,

EDWARD F. LONSDALE.

82, Guildford Street,
Dec. 9, 1843.

ACUTE LARYNGITIS.

To the Editor of the Medical Gazette.

SIR,

THE accompanying brief notes of a case of uncomplicated acute laryngitis are at your service, if you consider them deserving of a column in your valuable periodical. It seems desirable that cases of acute laryngitis should be accumulated. In the following case the good effect of general blood-letting was remarkable; and to this alone I attribute its satisfactory termination; not that I would in any case of acute inflammatory action omit to produce pytalism as speedily as possible. Of the means employed, the most important of which I have noted, as venesection, mercury, leeches, blisters; and others not noted, as saline mixture, with digitalis, hydrocyanic acid, diaphoretic doses of antimonial wine, nitre, and syrup of poppy, besides pills of extract

of henbane, and Dover's powder at bed-time, none seemed to be of any avail except the general blood-letting. With respect to the cause of the attack, its explanation appears easy, in the plethoric habit of the patient, the prevalence of cold damp weather, and residence on the banks of a (at that time flooded) river.—I am, sir,

Your obedient servant,

JOSEPH THOMAS, M.R.C.S.

Hay, Breconshire,
Dec. 22, 1843.

Nov. 17th, 1843. — Called to Mrs. Barker, housekeeper in a gentleman's family, æt. 40, of plethoric habit, whom I found with the following symptoms: Frequent, harsh, dry cough; occasional paroxysms of great difficulty of breathing, with crowing inspiration; sensation of oppression and heat about the throat; distressing cough, and feeling of suffocation produced by swallowing the least quantity of liquid. Pulse 120, and full. On applying the stethoscope over the larynx, a loud, harsh, penetrating sound was heard; whilst that of the trachea and bronchi was perfectly natural. There was no appearance of inflammatory action about the fauces.

The case was evidently one of uncomplicated acute laryngitis.

V.S. ad 3xvj. (Faintness produced.) Emp. Canth. sterno. Hyd. c. Cretâ, gr. v. 4tis horis.

18th. — Very slightly relieved.

V.S. ad 3xij. Leeches over larynx. Hyd. c. Cretâ, gr. iij. 4tis horis.

The quantity of grey powder in each dose was lessened by way of precaution, as I was told she had suffered severely from pytalism at a former period, when residing in the West Indies.

19th. — No better. Pytalism has appeared (produced by 32 grains of the grey powder.)

To discontinue the mercury. Leeches over the larynx. V.S. ad 3xij.

20th. — Cough less harsh; pulse 118. Altogether there seemed to be an improvement this morning; but in the evening the cough again became almost incessant, as well as harsh and dry. Pulse 130i

V.S. (lying down) to faintness.

About thirty ounces flowed. Neither this nor any other portion of blood taken exhibited the buffy coat.

21st. — Cough dry and frequent, but still there is an improvement. Pulse 120.

V.S. ad 3xiv.

22d. — Symptoms improving.

23d. — A decided amendment. Pulse 100. Cough softer, and for the first time followed by expectoration.

Emp. Canth. sterno.

24th. — Still improving. Pulse 90. Slept two or three hours at a time during the night. Previous to this the cough altogether prevented continuous sleep. The laryngeal sound is becoming natural.

From this date I discontinued my attendance, and left the patient in the care of her master, who is a surgeon, though retired from the fatigue and care of practice. From him I have occasionally learnt that the case continued to progress favourably under a mild restorative diet, and kind nursing.

CASE OF A LARGE CALCULUS REMOVED FROM BENEATH THE PREPUCE.

By JOHN MACPHERSON, Esq.

Civil Assistant Surgeon, Howrat.

(For the London Medical Gazette.)

JUNE 20, 1843. — G. D., æt. 45, a Hindoo, presented himself, complaining of inability to pass his urine freely. His urine has dribbled away from him for the last two years, causing much pain and inconvenience; he does not remember ever having been able to retract his prepuce; general health good.

On examination the testicle was found to be enlarged, and the skin of the penis, and especially the prepuce, much thickened and hypertrophied. No urethral orifice could be detected, and a hardened body was felt occupying the natural situation of the glans, and resembling it in general form.

With the view of exposing the glans, circumcision was performed, when a calculus was discovered retained *in situ* by the mucous membrane, which was white, tough, and thickened, having undergone the so-called cartilaginous degeneration of Andral.

The removal of the calculus and thickened mucous membrane exposed the urethral orifice, which was of its natural size, while the glans itself was

in a state of atrophy, almost obliterated by pressure.

The calculus thus found between the prepuce and the glans is whitish, homogeneous, and friable, consisting chiefly of phosphates. It is between a nutmeg and a walnut in size, and before it was dried, weighed almost half an ounce. It is spherical, flattened a little in front and behind. The surface in contact with the inside of the prepuce was smooth, the other one rough, where it was exposed to the action of the stream of urine.

Immediate and complete relief followed the removal of the calculus. Various opinions have been entertained regarding this very unusual form of urinary concretion.

1. As a collection of small calculi between the glans and prepuce is more commonly met with than a single large one, it has been supposed that they originate in the bladder,* pass along the urethra, but are not able to escape from beneath the tense prepuce, and therefore accumulate there.

2. In the case of a single calculus, it may be supposed that a single piece of gravel has passed from the bladder, and become impacted under the prepuce, and thus formed the nucleus for a large stone.

3. Some have regarded these stones as a diseased product of the mucous membrane of the glans and prepuce, which in these cases is generally altered in structure.

4. Others, again, believe that these calculi are formed where they are found, and are gradually formed by the process of cooling and straining which the urine must undergo in cases of extreme phimosis.

The last opinion accords best with the history of the case. The chief points of interest are, the size of the concretion, the atrophy of the glans, and the complete absence of ulceration, which the presence of a foreign body might have been expected to occasion, explained, however, by the state of the mucous membrane.

* The above is the substance of a paper read before the Medical and Physical Society of Calcutta, to which the calculus was presented.

CASE OF THE SUCCESSFUL REMOVAL
OF
A DISEASED OVARIUM,
OF
Two Years' duration.

By DR. FREDERIC BIRD,

Consulting Accoucheur to the Western Dispensary, Physician to the Metropolitan Free Hospital, and to the Westminster Maternity Charity, and Lecturer on Medical Jurisprudence at the Westminster Hospital.

(For the *London Medical Gazette*.)

— —
EARLY in the past month, I was consulted by Miss —, aged 21, who was the subject of abdominal tumor. The history of her case is the following:— With the exception of the diseases incident to childhood, her previous general health had been uninterruptedly good. At the age of sixteen the catamenial function was developed, and continued undisturbed until two years ago, when it became suddenly suppressed; three months after which abdominal enlargement commenced, but so gradually did it proceed, and so slight were the concomitant symptoms, that she was unconscious of the presence of disease, until her attention had been directed to her increasing size by those around her. She was at that time residing on the continent, where she placed herself under medical treatment, but receiving no benefit returned to England. The amenorrhœa was but of short duration, the catamenia reappearing after an interval of three or four months, and have since observed regular periods of recurrence; the secretion, however, has generally been greater than usual, and not unfrequently menorrhagic. The tumor, limited during the first four or five months to the hypogastric region, continued to acquire increased size, and during the last twelve months has occupied the entire cavity of the abdomen. Her general health has lately become much impaired, partly from the immediate effects of the disease, but in a greater degree by the hopelessness of relief, produced in her mind by the previous unsuccessful employment of remedies.

At the time of my first seeing her, there was a quick and irritable pulse, she was emaciated, her spirits depressed, and she suffered from frequent headaches; but, after having been informed

of the relief an operation might afford, these symptoms in a few days became much less severe. On examining the abdomen, the tumor was found to encroach considerably on the boundaries of the thorax, and to project outwards from the pubis for several inches. Fluctuation was distinct, and could be produced in equal degree at every part of the abdomen; percussion elicited a uniform dull sound, except at the left and partly at the right hypochondrium, where the tympanitic intestines gave rise to resonance; occasional nausea and vomiting of biliary matter, a torpid condition of the bowels, neuralgic pain in the course of the left sciatic nerve, and some general emaciation, were the leading symptoms present.

Having on two subsequent occasions carefully examined the condition of the abdomen, I came to the opinion that the disease was ovarian dropsy; that peritoneal adhesions were most probably absent; and that the tumor did not present any characters forbidding its extirpation. Before, however, suggesting the operation to her, I requested that she might have the advantage of the opinion of Dr. Hamilton Roe; who, after an examination of the case, confirmed me in the diagnosis, and not only sanctioned the performance of an operation, but prognosticated its successful issue. The removal of the tumor was then proposed, its attendant dangers and probabilities of success and failure clearly explained to her. A ready acquiescence followed, and Thursday, November 23d, was fixed for its performance.

The only preliminary measures were those employed in my former case, namely, the previous exhibition of a few grains of extract of colocynth, with blue pill, the use of a restricted diet, and artificially raising the temperature of the chamber.

Nov. 23d.—Favoured by the presence of Dr. Hamilton Roe, Mr. B. Phillips, Dr. Andrews, and Dr. Cape, the operation was thus performed;—The patient was placed transversely on the bed, her legs hanging over its side, and being supported by cushions to such a height as to preserve the tensesness of the abdominal parietes without rendering her position painful or uneasy. An exploratory incision, about an inch in length, was then made a little below the umbi-

licus, the peritoneal cavity opened, and the index finger introduced, for the purpose of ascertaining if adhesions were present at that part; and, having found that none existed, the incision was immediately enlarged to about four inches and a half. A little venous hemorrhage occurred, ceasing on the application of a cold sponge, whilst the tumor, pressing forwards, so effectually filled the opening, that the small quantity of blood escaping was completely prevented from passing into the peritoneal cavity. During the brief interval occupied in completing the incision, the distended cyst could be seen rising and falling synchronously with the respiratory action of the diaphragm. A strong pronged forceps was next made to grasp the sac, a trocar introduced, and exit given to clear, light, straw-coloured, and not viscid fluid. As its contents became evacuated, the cyst emerged from the wound almost altogether without any forcible traction, and a considerable portion of it was soon external to the abdomen; and fluid continuing to escape, the incision was constantly kept closed up by the graduated distension of the sac. Nearly the whole of the ovary being now withdrawn, I endeavoured to grasp the pedicle, but found that the attachment of the diseased mass to the uterus was almost sessile, nearly the entire length of the fallopian tube lying upon, and being inseparably connected with, the tumor, whilst the broad ligament appeared to have been carried forwards, and to have become intimately blended with the structure of the cyst. A common curved needle, with a strong silken ligature, was first passed beneath the fallopian tube, including what subsequently proved to be the principal artery. It was then firmly tied, and on being cut through, found to be well secured. A second needle, fixed in a handle and carrying two ligatures, was next introduced in such a manner as to divide the remaining part of the attachment into two portions, each of which was then separately and securely tied. In detaching the tumor some little difficulty was felt in procuring its separation without puncturing the depending portion of the sac; this arising from the small space existing for the application of the ligatures, and subsequent passage of the knife between them and the cyst. The entire

ovary having been now removed, the edges of the abdominal incision were then brought together by five interrupted sutures, and the ends of the ligatures fixed at the lower part of the wound. Cold water dressing was applied, a light linen roller drawn twice round the abdomen, and all strapping of the wound carefully avoided. The patient was then drawn to a more comfortable position in bed, and a few tea-spoonfuls of wine given her to assist in removing the slight faintness that occurred; but the fact of the tumor having been removed proved a much more efficacious restorative. The operation was borne with remarkable fortitude; scarcely a murmur escaped her, and the pulse at the conclusion was less frequent than before its commencement.

The disease was found to be seated in the right ovary; that of the opposite side, together with the uterus, was examined before closing the external wound, and found to be healthy.

5 o'clock, (two hours after the operation,) reaction is not yet established. Skin cool; respiration calm; pulse small but equal, ranging at 90. Slight pain about the wound.

A tea-spoonful of wine and water to be given occasionally.

7 o'clock.—Arterial action is now rapidly increasing, and with it the temperature of the body; radial pulsations feeble, somewhat irregular, in volume 100. Seven ounces of urine have been removed by the catheter.

R Morphiae Acetatis, gr. j.; Aquæ Flor. Aurant. ʒj. M. fiat haustus statim dandus. No food. A little rough ice to be given occasionally.

24th, 4 o'clock A.M.—Has not slept; heat of surface increased; pulse 150, readily compressed; tongue pale and moist; no abdominal tenderness or distension.

Morphiae Acet. gr. ss. ex Aqua Flor. Aurant. quâque semihorâ ad soporem.

7 A.M.—After the administration of the third dose of morphia, she slept for nearly two hours. Additional bed-clothes had in the meantime been thrown over her, and, whilst sleeping, most profuse perspiration took place; the pulse almost immediately falling to 134. On awaking, she expressed herself as devoid of all pain and uneasiness; her countenance free from anxiety, and her mind

unperturbed. At her desire the ice has been freely allowed.

9 A.M.—Continues to perspire; pulse has fallen to 124, and is soft and regular. Six ounces of urine by catheter.

2 P.M.—Has slept at intervals; surface moist, and scarcely above the natural temperature; pulse 116. Urine seven ounces.

7 P.M.—There is now some accumulation of flatus in the stomach or transverse colon, giving rise to local uneasiness and tendency to vomit; there is a marked distension of the epigastric region, but no tenderness on pressure; skin more hot, though perspirable; pulse irritable, 126. Small quantities of hot port wine and water, strongly spiced, were given, and quickly followed by copious eructations, and simultaneous relief to her symptoms. A few ounces of urine drawn off.

Morphia Acetatis, gr. j. horâ nona.

25th, 6 A.M.—About four o'clock she became restless, after having slept for an hour and a half, the pulse increasing in frequency, and assuming a different character, more full, less yielding to pressure, and 130; skin hot, and more dry; pain in the head, and intolerance of light, and nausea, but no vomiting. There is now no abdominal pain on pressure or otherwise; the tympanitic distension has disappeared, and although there is at present no evidence of inflammatory action, yet her general condition is that which would favour its development. With the view of anticipating any such attack, and to lessen the undue action of the arterial system, I directed that blood should be taken from the arm by a free orifice, until a decided impression should have been made on the circulating force. When about sixteen ounces had been withdrawn slight faintness occurred; but, quickly passing off, was followed by marked amelioration of symptoms.

Morphiae Acetatis, gr. ss. statim et repetatur post horam si opus fuerit.

Calm sleep succeeded to the first dose of the morphia, lasting for two hours; and at 1 o'clock P.M. she presented a decided improvement. Healthy action of the skin was going on; pulse 124, equal and soft; countenance animated by hope, and voice cheerful. Since the last report she has taken

Two ounces of water arrow-root, a cup of tea, a little dry toast, and ice.

The urine has been removed by catheter as often as any necessity for doing so existed; it is healthy both in quantity and in character. The upper part of the wound has healed, the lower suppurates. The blood drawn has been allowed to remain until the present time; it is neither cupped nor buffed, but presents an unusually large proportion of fibrin.

26th, 2 A.M.—As night approached some restlessness occurred; but, after the administration of half a grain of morphia, she slept tranquilly for two hours. Pulse 128. Urine secreted during the last twelve hours, 16 ounces.

12 A.M. Pulse 116; skin and tongue natural. The bowels have not been relieved since the day preceding that of the operation.

R Ext. Coloc. Co. gr. viij.; Pil. Hydr. gr. ij.; Olei Cassiæ, Mij. Fiat Pilulæ duæ hæc nocte sumendæ. For diet a little vermicelli, tea, and dry toast, with a small quantity of arrow-root.

27th, 5 A.M.—Passed a rather restless night, but is now in the same state as yesterday. The bowels have not acted.

Enema Olei Ricini statim injicienda et repetenda post horas quatuor si ops sit.

Vespere.—Three enemata were employed before the bowels were relieved; when four copious scybalous evacuations resulted, accompanied by the passage of much flatus. Pulse 110.

28th.—Disturbed, during the night, by the bowels again acting; the evacuations presenting a much more healthy character.

Allowed veal broth with vermicelli, in addition to former diet.

29th.—Passed a tranquil night, and now complains only of her still spare diet. Pulse ranges at 100.

30th.—Bowels not having been relieved, an enema was made use of, and followed by two dejections.

Dec. 2d.—Rapidly improving; pulse 84; bowels not acting.

R Magnes. Sulphatis, ʒss.; Acid. Sulph. Dil. ʒj.; Syr. Aurantii, ʒss.; Infus. Rosæ Co. ʒvij. Fiat Mistura ejus capiat cochlearia ampla duo bis terne die. For diet, a mutton chop, arrow-root with milk, tea and dry toast, daily.

14th.—The notes made since the date of the last report serve but to mark the speedy and uninterrupted approach of convalescence. Increased diet has been

cautiously allowed, and is now unrestricted. The temperature of the chamber, which at the time of the operation was 85° F., was, after a lapse of three days, reduced to 70°, and now does not exceed 60°. She has for several days quitted her bed; menstruation has been normally performed; the secretions are healthy; and she is rapidly gaining strength. The abdomen, which for the first few days after the removal of the tumor, was much retracted, has now, from the return of the viscera to their natural situations, become more full. One of the ligatures came away on the fourteenth day after the operation, the remaining ones on the seventeenth; the external wound has quite healed, and she is now in all respects perfectly well. The dimensions of the abdomen before and after the performance of the operation are the following:—

From ensiform cartilage to pubes, before operation, 15½—after operation, 10½.

Circumference of the abdomen, before operation, 39—after operation, 22½.

The tumor was of an ovoid shape, having a regular outline at its superior portion, whilst the inferior was marked by elevations and depressions corresponding to the unequal pressure caused by the surrounding pelvic viscera. It consisted principally of one large cyst, having walls of various density and structure, presenting generally a thickness equal to the fourth of an inch, but in some parts had acquired twice that measurement. In these latter portions large plates of atheromatous deposit existed, in several parts of which points of ossification could be observed. No peduncle was attached to the tumor, unless a slight projection of the fallopian tube can be called such. The broad ligament was continuous with, and appeared to form a part of, the sac. The fallopian tube was also closely adherent throughout, its structure in several parts being blended with that of the cyst; it was elongated, stretching across the posterior part of the tumor in a tortuous manner to the extent of nine inches.

The sac was very vascular, each portion of it being covered by a dense network of vessels, formed by the numerous ramifications of one large and two smaller arterial trunks. The former equalled in size the brachial artery, and passed, in form of a cincture, almost entirely round the tumor, pursuing one-

third of its course without dividing, but giving off many lateral vessels; the two smaller arteries followed a different course, being very tortuous, and uniting on either side by means of their ramifications.

Near the inferior part of the cyst, and within it, were developed several smaller cysts closely adherent to the parent sac, and containing fluids of varying densities: a small portion of solid matter was also present. The fluid contained in the primary cyst had a light straw colour, transparent, and not viscid, having a strong saline taste, containing no free albumen, and having the specific gravity of 1.007. The total weight of the tumor amounted to twenty-seven pounds.

REMARKS.—Although it is not my present purpose to make any lengthened remarks upon the general question of extirpating diseased ovaria, I am yet unwilling to allow the present case to be recorded without briefly alluding to the evidence it affords in favour of the method of operating I have ventured to advocate. The necessity for having recourse to what has been called the major operation, or large abdominal section, is far from being so well established as some recent writers have affirmed, and although relative success may have attended operations of this kind, it still remains a matter of high importance to inquire to what extent such success extends. Unless the ovarian tumor be nearly altogether free from contained fluid, the great incision recommended cannot be required for the removal of the diseased organ. It is quite true that by such procedure the operation may be rendered more easy of performance, and the tumor may be removed in its unpunctured state; but in what does this latter circumstance benefit the patients in whom it may occur? In the case I have here related, the size of the tumor was very considerable, its attachment to the uterus was not that commonly met with, and presented somewhat greater difficulty in the way of removal; nevertheless this was safely effected, and the operation completed by an incision of comparatively small size. Had a greater amount of solid matter been found than was anticipated, and if of too large a size to remove otherwise, the elongation of the abdominal incision would have

been but a very simple proceeding. Again, if it be a matter of importance to prevent the entrance of air into the peritoneal cavity, then is an incision of medium size best calculated to effect such object. In both cases in which I have operated a portion of the cyst has escaped from the abdomen immediately after the incision was made, thus dividing the tumor into two portions, an internal and an external, the connecting portion, or neck, being by the law of the equality of fluid pressure kept constantly and accurately adapted to the walls of the aperture, in consequence of the continued passage of fluid from the cavity of the sac; whilst, in the instance of the very large incision, it is difficult to imagine how this can be effected, as after the removal of the tumor the consequent flaccidity of the abdominal walls would render the accurate adaptation of the edges of the wound a matter of the greatest difficulty, at least as relates to the instantaneous manner in which it must be performed in order to prevent the admission of air.

It is, however, in the subsequent condition of the abdominal walls that a strong argument may be found against the employment of very large incisions; re-union of the abdominal parietes after the receipt of such injuries is not found to take place in so complete a manner as to prevent the future occurrence of visceral protrusion, and hernia is far from an unfrequent consequence. It is, I believe, by the employment of an incision of moderate size, sufficiently large to allow of the introduction of the hand of the operator, if required, that the probabilities of complete success will be enhanced. The form of operation to which the term *minor* has been applied is insufficient, inasmuch as the employment of mechanical force, from the smallness of the incision, can scarcely be avoided. The question of the influence of age upon the success of the operation is one of much interest, more especially as the removal of ovarian disease is a still greater desideratum in the young than in the more advanced in life. Considerations other than these of the ultimate effects of the disease in earlier life, exert a powerful influence, and in the lady whose case I have related, the consciousness that the deformity produced by her malady rendered her *hors de société*, formed an important

element in the self-conducted argument that induced her to submit to, and, indeed, to seek the operation. The proneness to inflammation was not greater than has been observed in persons of more advanced age, and that source of danger once passed, her youth doubtlessly exerted considerable influence in causing her rapid recovery. That disturbance of the general system, and a tendency to increased action, is to be expected in persons of all ages as one of the immediate results of operations of this kind, is not, I conceive, solely attributable to the shock produced, or to the exposure of a large serous surface, but that another cause is to be sought for in the fact that a free secretion that has been going on uninterruptedly for years is suddenly arrested by the extirpation of the diseased organ; the amount of circulating fluid before necessary for its support is thrown back upon the system; increased action results, which, favoured by collateral influences, may terminate in inflammation.

With reference to the probabilities of success and of failure in future cases, but little can yet be said. So far as the different methods of operating are concerned, it will, I doubt not, be hereafter found that the chances of success are against the employment of the large abdominal section. Both these questions can alone be satisfactorily solved by statistical records; and, as a very important feature in their construction, it is most essential that all cases be invariably and faithfully reported, not only as regards their success *quoad* the operation, but also as relates to the complete re-establishment of health. It is painful to imagine that successful cases can be published, re-published, and circulated most extensively, both within and beyond the pale of the profession, whilst those in which death may have resulted as the consequence of an operation, shall be passed over untold and unrecorded, leaving no evidence of their ever having occurred beyond that of the uncertain tongue of rumour. To record faithfully, and with equal publicity, successful and unsuccessful cases is, in the present state of our knowledge, a moral obligation, from the full performance of which no honourable mind would shrink.

38, Craven Street.

ON THE EFFECTS OF THE COD'S LIVER OIL UPON STRUMOUS AND OTHER DISEASES.

To the Editor of the Medical Gazette.

SIR,

VARIOUS notices of the effects of the cod's liver oil upon strumous and other diseases having come under my observation, I determined on testing its medicinal virtues when an opportunity offered. If you think that the subjoined notes of cases treated by me at the Royal Sea Bathing Infirmary, Margate, during last summer, of sufficient interest, will you have the goodness to give them a place in your journal? I have prefaced them with some observations on its effects, which, I think, are warranted by the result of the treatment. Of their correctness I leave your readers to judge, from the recital of the cases before them.—I am, sir,

Yours very obediently,

WILLIAM OLIVER CHALK.

3, Nottingham Terrace, York Gate,
Regent's Park,
December 18th, 1843.

REMARKS.—It would seem that Ol. Jecoris Aselli is an active therapeutic agent in strumous, rheumatic, and some skin diseases; and that its revival as a remedy is likely to prove of great service. It cannot be considered as a merely dietetic* agent, cases 8, 15, 33, being of themselves sufficient to negative the conclusion. It possesses considerable power in allaying the diseases of the joints, especially strumous and rheumatic, and that with a rapidity unequalled by most other medicines. Tubercular depositions are absorbed under its influence (cases 15, 26, 27). Even in the lungs† it appears to have the power of arresting, or at least of modifying, the deposit (cases 4, 20, 30). Scrofulous diseases of the bones are relieved by it (cases 13, 23). Faulty secretions are quickly changed to healthy, especially the hepatic. Some experiments were made on patients

* Vide Br. and For. Quarterly Journ. Jan. 1842, page 200. Review of Dr. Bennett's work on the cod's liver oil.

† I speak with caution on this point, as my observations are not sufficiently numerous to arrive at any positive conclusions; yet they seem to me sufficient to render a further and separate inquiry of value, especially as it has been observed by others.

where no local affection existed, with a view to ascertain its effects on the biliary organs. Its success, in several instances, was complete, in changing the varied and clay-coloured motions of serofulous habits to a healthy condition. With children the exhibition of the oil was commonly followed by relaxation of the bowels; with adults it frequently produced constipation. One of the most remarkable properties is its power of inducing *embonpoint*, and of restoring a healthy hue to the countenance. The number of patients treated with Ol. J. A. amounted to between eighty and one hundred, of whom a large majority obtained decided relief. A great deal of difficulty was at first experienced in the administering of a remedy so disgusting and nauseous; nothing, I believe, could have induced many to take it but the opportunity they had of observing its good effect on others. Since my return to town, I have endeavoured to obtain a purer oil, for, however useful as a medicine, it would be impossible to bring it into general use unless deprived of its impurities. After examining several specimens, I have found that prepared by Mr. Wright, of 54A Gloucester Place, Portman Square, to be the best, and its qualities unimpaired by the process employed for its purification. He states, as the result of his experiments, that he has obtained oils of various qualities, some of them quite inert. The liver of the milter cod yields the strongest oil, and darker in colour than that of the spawner. The two specimens now by me are exceedingly pure, nearly inodorous, and of a crystalline clearness. One is of a brown colour (the milter), the other of a light yellow (the spawner); the specific gravity of the former is .921.5, temp. 64; that of the latter .919, temp. 64. The quality of the oil is considerably impaired when a high temperature is employed in the manipulation. The object in giving publicity to these cases is not to speak of the cures performed by ol. jecoris aselli, for they will be found comparatively few, but to call the attention of others to the fact that it does yield relief to a class of patients whose diseases too often baffle the attempts of the most enlightened practitioners, and to induce them, when opportunity offers, to test its virtues for themselves. The seven last cases detailed are given

merely as examples of the ill effects which sometimes ensued whilst prescribing it at the Infirmary.

CASE I.—James Rush, æt. 29, admitted May 16, 1843, suffering under strumous synovitis of the right ankle, complicated with rheumatic action. The tibia is considerably enlarged, and the periosteum much thickened at the articulation; there are several sinuses on its outer and inner side, discharging a profuse and unhealthy pus. He suffers great pain at times, and is in a very weak and emaciated state. After undergoing the usual plan of treatment, with little or no relief, until July 20th, he began taking Ol. Jecoris Aselli, ʒss. ter quotidie, which he continued without intermission until September 26th, when he was discharged from the infirmary. He states that his general health has not been so good as it is now for years; his appetite is excellent, the tongue clean, and the pulse good; he has gained flesh surprisingly, and his whole appearance is much altered for the better. The ankle is smaller, and free from pain; the discharge, formerly so copious, is now slight and healthy; two of the sinuses are healed, and he has regained partial motion of the joint. He says that the oil produced a sensation of nausea for the first few days; after that time it ceased to be disagreeable to him. He had not taken it more than a day or two before there was a visible alteration in the local and general symptoms for the better.

CASE II.—William Delay, æt. 26, admitted August 4th, suffering from extensive strumous ulceration of the right side of the face and neck, extending as low down as the clavicle. The head is inclined to the shoulder of the side affected. He is in a very weak and debilitated state. He attributes his present symptoms to a severe attack of erysipelas in February last, the ulcers having formed about fourteen days after his recovery from it.

August 5th.—A suitable local treatment having been adopted, Ol. J. A. ʒss. ter die was prescribed. The first dose produced a disposition to sickness, and recoiled on the stomach, especially after meals; these sensations wore off in two or three days. He has continued taking it, without intermission, up to the present date, October 19th. He states that his general health is greatly improved, and he thinks that he has gained full a stone in weight. The tongue is very clean, and the pulse natural; his countenance is florid and healthy. Several of the ulcers are healed, and the remainder are healing; that on the neck, which was nearly as large as one's hand, is diminished to half its size. He says that he has quite conquered his repugnance to the oil.

CASE III. — Ed. Curtis (out-patient), æt. 24, admitted October 9th. Has been labouring under strumous synovitis of the right knee for the last four years. The parts are swollen, hot, and painful on pressure; the slightest attempt at motion causes severe pain. He complains of general weakness; the pulse is quick and feeble, and the tongue furred. He was ordered the use of the warm sea-water bath three times a week, to surround the joint with an ointment of the iod. of mercury, and to rest the limb as much as possible.

October 12th. — The symptoms having increased rather than diminished, Ol. J. A. ʒj. ter die was prescribed, which he took without producing any disagreeable effects, such as nausea, &c. He was discharged at the closing of the infirmary, October 23d. He states that he feels stronger, and that his appetite has increased. His general appearance is much improved. The tongue is clean, the pulse firmer and less frequent, the knee is not so swollen or painful, and the heat has subsided. He can bear a considerable degree of motion without experiencing pain.

CASE IV. — Thomas Haynes, æt. 19, admitted May 12th. Is phthisical. He has occasional fits of coughing, accompanied by purulent expectoration. There is a cavity at the summit of the right lung, pectoriloquy being audible over a considerable space below the clavicle. A portion of the left lung is solidified from deposition of tubercular matter. The sound is very dull at the upper part of the thorax. A mucous rhonchus is heard at different points on both sides of the chest. He is in a state of great debility; the tongue is furred, bowels inactive, appetite defective, pulse frequent and feeble; he has febrile accessions, followed by profuse sweats; he is suffering from caries of the left os calcis; the outer ankle is hypertrophous, and there is a large foul ulcer discharging a highly foetid pus; the metatarsal bone and phalanges of the right great toe are also the seat of caries, accompanied by enormous hypertrophy of the soft parts; there are several unhealthy ulcers situated over portions of denuded bone. As very slight relief had been afforded to the general or local symptoms, especially to the former, up to July 18th, the oil was prescribed on that day in half-ounce doses three times daily. Nausea and catharsis followed its exhibition for a day or two. He has continued taking it, with slight intermission, up to the present date, October 19th. He states that his general health is greatly improved, his appetite has increased, and he has gained flesh. The pulmonary symptoms are rather ameliorated than otherwise, the cough having nearly subsided; the hypertrophy of the ankle and

toe greatly relieved; the ulcers are healthy, and have partially healed; that on the ankle is much diminished.

CASE V. — Richard Jones, æt. 20, admitted August 23d, 1843. Psoriasis of a very severe character occupying the hands and wrists, from which he has been suffering, at different periods, for the last four years; the face is also slightly affected. He attributes its occurrence to the drinking of a great quantity of cold water whilst under the influence of profuse perspiration, in the month of July 1839. The hands and wrists are covered with thick scales and deep fissures, producing pain and violent itching. He was ordered to use the warm sea-water bath three times a week, at a temperature of 98°, and to remain in only five minutes. An ointment of the iod. of mercury, and subsequently that of iod. of sulphur, was applied to the eruption. The sulph. iod. was exhibited internally, and afterwards changed for O'Donovan's solut. hydriodatis arsen. et hyd. combined with compound decoction of sarsaparilla and inf. of colomaba. These remedies were persevered in until September 22d, without producing any beneficial results. Ol. J. A. in doses of ʒss. three times a day, was prescribed. The local treatment consisted in the application of ung. cetacei, merely to allay the itching and soften the scales. He continued taking Ol. J. A. until the day of his discharge, October 19th. The only trace of the disease now remaining is slight articular efflorescence. He says that he has never been so free from it since its first appearance. He observed an amelioration in the local symptoms after he had taken the oil about a week. For the first two or three days it recoiled on the stomach, and acted freely on the bowels twice during the day. He has gained flesh rapidly, and his countenance is florid and healthy.

CASE VI. — John Warren, æt. 18, admitted Sept. 8th, suffering from lepra vulgaris occupying the surface of the body and the extremities, and affecting the scalp. The disease made its appearance five months since, after a severe cold. The warm salt water bath was ordered three times a week, and persisted in until Sept. 25th, during which time the eruption had undergone an alteration for the worse. The use of the bath was suspended, and he took Ol. J. A. ʒss., which produced slight sickness, and for the first week he could only take it twice a day, after which he conquered his dislike, and continued it three times daily up to the present date, Oct. 19th. He has improved rapidly; the eruption is fast disappearing, the scalp and forehead are free from it. (It should be mentioned, that to these parts he has applied Ung. Hyd. Iod. every night for some time past.) He states

that he has gained flesh to such an extent since taking the oil, that his clothes scarcely fit him. His general appearance is that of excellent and robust health.

CASE VII.—Henry Cracknell, æt. 49, admitted August 8th. Paralysis of the upper extremities. He can move the arms slightly; the wrists are powerless; his speech much affected. He states that at the latter end of February last he suffered from a violent attack of rheumatic fever, in which the abdominal muscles were severely implicated, accompanied by frequent vomitings. In about three weeks from the commencement, he began gradually to lose the use of the shoulder, the wrists, and finger joints, suffering at the same time acute pain in them. Having partially recovered from the rheumatic attacks, at the end of July following he had a fit, after which his articulation became imperfect, and the paralysis more complete. He was ordered the warm sea-water bath three times a week, at 98 degrees of heat. This was changed for the douche bath to the upper extremities, and the warm sea-water bath twice a week, at the same temperature. On September 6th the oil was prescribed; the first dose produced violent vomiting, and he could not make up his mind to take it again for some days. He recommenced, however, with the same quantity (3ss.), and continued it three times a-day, without experiencing any disagreeable effects, up to the present date, October 19th. He has recovered the power of utterance, does not suffer any pain, is able to raise his arms (the paralysis being confined to the wrists, which, however, are much stronger), and has gained flesh considerably. He says, that after taking Ol. J. A. for about a fortnight, the rheumatic pains were relieved, and his appetite increased.

CASE VIII.—Joseph Allton, æt. 37, admitted September 15th: chronic rheumatism of nine weeks' standing, affecting the knees and legs; he suffers severe pain, with total inability to walk or stand; he is much reduced, and has not been able to quit his bed since he was first attacked.

16th.—R. Ol. Jecoris A. ʒss. ter die.

After he had taken it about two days, so much relief was obtained, that he was able to walk across the ward, assisted by two persons. He continued taking the oil with regularity up to October 13th (the day of his discharge). He had gained flesh and strength surprisingly, and was able to walk on crutches free from pain. He stated that he took the oil in larger doses than was prescribed, viz. from ʒj. to ʒij., and that he avoided the nausea, &c. it first occasioned, by smoking. Considering the severity of the case, and the short time of treatment, the improvement was remarkable.

CASE IX.—Henry Meyer, æt. 21, admitted as out-patient August 29, 1843: rheumatic synovitis of the left knee; it is enlarged, and very much contracted; the motion of the joint is greatly impaired; any attempts at flexion or extension give pain: this state of the articulation was produced by a severe attack of rheumatic fever in July 1842.

Sept. 7th.—Was ordered to apply the Ol. J. A. every night as a liniment to the knee, and to take a table-spoonful three times a day. For the first two or three days it created a sensation of nausea.

Oct. 11th.—The knee is greatly relieved, although it remains much contracted; he has regained a good deal of motion, and can bear the attempt at flexion or extension without much pain. He has gained flesh rapidly during the time he has been taking the oil; his countenance bears the hue of health; the tongue is clean, and pulse natural. He says that he has never felt so well at any period of his life.

CASE X.—John Chapman, æt. 32, admitted May 15, 1843: rheumatic synovitis of the left knee; the motion of the joint is greatly impaired; the patella is immovable from ankylosis. He complains of pain and general weakness of the limb; he is able to walk a little by the aid of a stick. This state of the articulation was induced by an attack of rheumatic fever during the winter. After persevering in the usual remedies with some benefit until August 12th, the oil was prescribed in doses of ʒvj. three times a day, and to be rubbed on the knee every night. The usual symptoms followed its first exhibition; he could not take it for more than a week consecutively, as at the end of that time he suffered from nausea and constipation; he was able to resume it, however, in two or three days after the bowels had been moved by an aperient. In this way he has taken the oil with great benefit to himself up to the present date, October 23d. He says his general health is excellent, and that he has gained flesh considerably. The knee is of its natural size, and free from pain; he has recovered a great deal of motion; the only obstacle to the perfect action of the joint being the fixed state of the patella: he can walk two or three miles with ease.

CASE XI.—John Borowski, æt. 30, admitted August 10th: chronic rheumatism, affecting severely the joints of the fingers and toes, producing great deformity of the latter, by distension of the capsular ligaments and partial dislocation. He complains of pain in the shoulders and wrists: these symptoms are consequent on an attack of rheumatic fever five years since. In addition to the warm bath, from which he had derived much relief, Ol. J. A. was prescribed September 15th: for the first few days it acted freely on the bowels.

Oct. 6th.—The deformity of the articulations was much lessened: he suffered scarcely any pain; his general health greatly improved, and he had gained flesh during the last three weeks.

CASE XII.—Richard Dyer, æt. 23, admitted September 6th: is suffering severely from chronic rheumatism in the hands, knees, feet, and ankles; he has been so affected nine months.

26th.—Having derived little relief from his previous treatment, he was ordered *Ol. J. A. ʒij. ter die*. The first few doses produced constipation, and recoiled on the stomach; after this his appetite began to improve; his countenance became obviously altered for the better; the rheumatic pains were greatly relieved, and he was enabled to walk free from pain until October 8th, when, the weather becoming suddenly cold and boisterous, he had a relapse.

October 13th.—He is now getting better, and states that he has on the whole derived great benefit from the oil.

CASE XIII.—John Cross, æt. 17, admitted May 30th: necrosis of the right femur, consequent on scarlet fever twelve months since: strumous ulcers on the inner ankle of the same limb.

August 17th.—He took cold, which terminated in an attack of rheumatic fever. On the subsidence of the febrile symptoms, he remained in a very weak and emaciated state.

Sept. 20th.—*R. Ol. J. A. ʒss. ter die*.

It has been taken with regularity up to the present date, October 24th. The ulcers are fast healing: his general health is greatly improved; he has gained flesh considerably, and his countenance wears the hue of health.

CASE XIV.—Thomas W. Skeys, æt. 10, admitted May 9th: strumous hypertrophy and ulceration of the index finger of the right hand, with caries of the first phalanx. The right great toe is similarly affected. There is an unhealthy ulcer on the outer side of the left heel, with caries of the *os calcis*. These symptoms are accompanied by great derangement of the digestive organs, and general debility. After undergoing a course of treatment which consisted in the application of leeches to the epigastrium, a careful regulation of the bowels by aperients, enemata, alteratives, sarsaparilla, &c. with very decided relief, on August 24th three drachm doses of the oil were ordered to be taken three times a day, as the general and local affections seemed to have been retrograding during the preceding ten days.

Oct. 16th.—He has continued it regularly up to the present date. Hypertrophy of the index finger and great toe very much relieved (the first phalanx has been removed from the former); ulcer on the heel diminished in size, and healthy. His general appearance has undergone a great alteration

for the better; he has gained flesh; the tongue is clean; pulse normal; the evacuations, previously clay-coloured and changeable in appearance, are now healthy. He states that the oil was not disagreeable to him, and that he always felt exhilarated after taking it.

CASE XV.—Robert Selby, æt. 14, admitted May 12th. Expanded condyles of the femur and head of the tibia, from depositions of tubercular matter in their cancellous structure: he suffers constant and severe pain in the articulation: the knee is much contracted; there is also a large chronic abscess on the anterior part of the thigh, just above the joint: these symptoms are accompanied by great constitutional disturbance, viz. hectic fever, profuse sweats, and sleepless nights, loss of appetite, furred tongue, irregular state of the bowels, and clay-coloured evacuations; he is greatly emaciated, and appears to be fast sinking under the disease; he has been ill seven months. The stethoscope does not afford any evidence of tubercular deposit in the lungs, although the general aspect of the patient would lead one to suspect it. As no alleviation had been afforded either by the general or local treatment, and his sufferings being great,

July 5th.—A table spoonful of *Ol. J. A.* was ordered to be given three times a day. The knee, at this time, had greatly increased in size: the parts were hot, tense, and extremely painful; the leg was twisted, and flexed on the thigh, giving rise to partial dislocation of the head of the tibia; the least motion or jarring of the body caused severe pain; it was distressing to observe the anxiety and watchfulness induced (on the part of the patient) by the last mentioned symptoms. On visiting him the following morning at 11 o'clock, I found that his bowels had been freely relieved twice previous to my visit, and that only one dose of the oil had been given the day before, as it produced great nausea, and three copious and highly fetid stools. The knee was freer from pain, and the countenance less anxious. *Ol. J. A. ʒij. ter die* was now prescribed: he continued taking it with regularity for a fortnight, with considerable relief to the local and general symptoms, when the stock of oil having been exhausted, he was obliged to discontinue it for three days (during this short interval the condition of the knee had altered for the worse, there were increased pain, heat, and tumefaction); a fresh supply having been procured, the dose was augmented to ʒss. which he continued without inconvenience up to the present date, Oct. 19th. All pain in the knee has ceased, the condyles of the femur and the head of the tibia are much diminished; these now retain their relative and normal situations; the

contraction is very slight; he can put his foot to the ground, and walks by the aid of crutches free from pain; the tubercular deposit above the knee is nearly absorbed; his general health is excellent; the tongue is clean, pulse natural, alvine excretions regular, and of a healthy colour; he has gained flesh to such an extent as to cause great surprise amongst those who had previously witnessed his formerly emaciated condition.

CASE XVI.—W. H. Sweeney, æt. 8, admitted August 4th: diseased state of the left hip-joint. He complains of great pain on the least movement; abscess is forming on the upper and outer side of the thigh; his general health is much impaired; the pulse feeble; tongue furred; alvine evacuations clay-coloured; appetite defective; countenance pallid. As the case had gone on very unfavourably, October 12th. Ol. J. A. ʒiij. three times daily was prescribed. He was at this time suffering from hectic fever, profuse discharge from the abscess, and severe pain in the articulation; the soft parts in the vicinity of it were hot, swollen, and painful; the slightest movement of the limb caused severe pain. Two doses of the oil were given in the course of 24 hours, and produced decided relief. It was afterwards taken regularly up to the present date, Oct. 21st. He is now able to sit up with his clothes on; the soft parts have recovered their natural state; the abscess is nearly healed; he suffers no pain, except an attempt be made to move the limb by flexion or extension; the febrile symptoms have subsided; the tongue is clearing; the evacuations are more healthy, and no longer clay-coloured; his appetite is very good; the countenance is calm, presenting a remarkable contrast to its appearance of suffering a short time since.

CASE XVII.—Thomas George Kempson, æt. 9, admitted May 8th: morbus coxæ (on the left side) in its suppurative stage, with consecutive dislocation of the head of the femur on the dorsum ilii; strumous synovitis of the right knee-joint; it is much contracted; the condyles are enlarged. He suffers great pain, and cannot sleep at night. He is in a very debilitated state: the hip has been bad four years. The local and general symptoms improved, soon after his arrival, under the influence of the warm and douche baths, mild aperients, and the application of ung. hyd. iod. to the hip and knee. He continued under this plan of treatment, with little variation, until October 4th, when the knee became again very painful. Ol. J. A. ʒss. ter die, was given, and continued up to the present time (Oct. 23d). The hip is nearly healed; the knee has undergone a remarkable alteration for the better; it is smaller, less contracted, free from pain, and a considerable degree of motion has been

recovered. His general health has improved very much since taking the oil.

CASE XVIII.—James Thonboro', æt. 7, admitted September 4th: diseased state of the right hip of twelve months' standing; suppuration has commenced in the immediate vicinity of the joint. He complains of great pain, especially on the slightest movement: his general health is impaired, and he is emaciated.

21st.—Ol. J. A. ʒss. was ordered three times a day. The first dose made him very sick, and acted copiously on the bowels; subsequently no such effect was produced. An almost immediate alteration for the better was perceptible in the general and local symptoms, and he has continued to improve up to the present time, Oct. 24th. The hip is free from pain, and the suppurative process has been checked; his health is much altered for the better; the tongue is clean; pulse natural; appetite excellent; bowels regular: he has gained flesh surprisingly.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Elements of Natural Philosophy: being an Experimental Introduction to the Study of the Physical Sciences. By GOLDING BIRD, A.M. M.D.; Assistant Physician to Gay's Hospital, &c. 2d Edition.

THE appearance of a second edition of this very excellent work will be hailed with pleasure by every one interested in the education of the young aspirant for medical honours, as it proves, better than any other argument can, the increased attention now deservedly paid by the profession to the collateral branches of knowledge: sciences which, although not absolutely necessary in enabling a physician to treat pneumonia, or a surgeon a broken leg, aid alike the doctor and the patient, by enabling the former to take sounder and more enlarged views of the dynamic forces ever active in the human frame, of which the latter receives indirectly the benefit. This work now consists of twenty nine chapters, of which nine are devoted to the physics of ponderable matter, the other being occupied with an account of the physics of the imponderable agents. A considerable portion of the latter part appears to have been re-written, and we have

been much pleased with the clear and succinct manner in which the author has treated the difficult and abstruse subjects of the plane and circular polarization of light. It is obvious that no review of a strictly descriptive work of this kind can be attempted; but, from a careful perusal of it, we are convinced that this edition is well calculated to maintain the scientific fame of its talented author; and we strongly recommend it to the student, as not only the best, but almost the only work to which he can refer in commencing the study of his profession, or in preparing himself for his examination.

A Dictionary of Practical Medicine,
 &c. &c. By JAMES COPLAND,
 M.D. F.R.S. &c. &c. Part IX.

THIS part, which has just appeared, completes the 2d Vol. of Dr. Copland's Dictionary. It contains the conclusion of diseases of the lungs, and embraces a variety of articles, the principal of which are the Lymphatic and Lacteal Systems—mamma, measles, melanosis, menses and menstruation, mesentery, muscular structure, nerves, neuralgia, œsophagus, osseous system, and ovaria.

The articles are written in the same general manner as in the preceding parts, and are quite calculated to support the high reputation which the work has so deservedly acquired.

The Oculist's Vade-Mecum: a complete Practical System of Ophthalmic Surgery. With numerous woodcuts and coloured engravings of the diseases and operations on the Eye. By JOHN WALKER, Surgeon to the Manchester Eye Hospital; formerly Lecturer on the Eye in the Manchester Royal School of Anatomy and Medicine. London: 1843.

THIS work is essentially practical, and, we think, is likely to be very useful, embodying, as it does, the results of twenty years' experience in the branch of which it treats.

In such a work the great object is not to expand, but to select and condense as much as is consistent with perfect perspicuity—an object which the author appears to us to have in a great measure succeeded in accomplishing. The plan adopted is that of avoiding abstruse disquisitions, and giving clear

practical descriptions of the phenomena, and an account of the most appropriate remedies. After describing the diseases of individual parts, the organ is next considered as a whole; after which the author proceeds to describe the diseases which affect its appendages.

We find at the commencement another important practical description; that, namely, of the proper mode of examining the eye, and this is the only portion which we have room to quote.

"Before, however, entering into a detailed account of the various forms of conjunctival inflammation, it may be desirable to make a few observations on the best mode of examining the eye when the seat of this morbid action.

"It is obvious that the greatest delicacy ought to be exercised in conducting the process of examination. This is important, not only on account of the feelings of the patient, but also the reputation of the surgeon; for we know that patients often form a favourable or an unfavourable opinion of the practitioner, according as he manipulates the organ in a gentle or rough manner.

"The best position for a patient under examination is, seated in a chair with a high and gently-reclining back, against the top of which his head should repose; the chair being placed either just before or on one side of the window. A room facing the north is to be preferred, as the surgeon is then less likely to be annoyed by the reflection of the sun's rays.

"In some cases, the patient will hardly be able to expose the eyes at all to the light; in others he will have no difficulty. It will be proper never to remain satisfied with the examination of merely that part of the eye which is usually exposed to view; on the contrary, we must never omit to scrutinize minutely every part of the surface of the organ. Of course a superficial view must first of all be taken, but this will be not sufficient. In our special examination, we must first look to the state of the conjunctiva of the cornea; any deviations from the natural condition should be carefully noted.

"To obtain a view of the portion of conjunctiva covering the inferior half of the eye-ball and the inner surface of

the inferior eye-lid, is, generally, a matter of no difficulty, when there is no intolerance of light or any morbid sensibility, as, for this purpose, it is merely necessary to place the tip of the fore-finger, keeping the sharp edge of the nail away, against the central portion of the outer surface of the lower lid, just below the ciliary margin, and then draw it gently downwards. Eversion of the lid is produced by this operation.

"In order to obtain a view of the conjunctiva of the superior half of the globe, and of that of the upper eye-lid, some nicety of manipulation is requisite, because the upper is much more irritable than the lower eye-lid, and it also possesses a much greater share of mobility. We may, however, usually accomplish its elevation to such an extent as to admit of the upper half of the front of the eye-ball being brought into view, by placing the thumb against the outer surface of the lid, in the same manner as the finger has been directed to be applied to the lower lid, and raising it gently towards the eye-brow, at the same time requesting the patient to turn the eye downwards.

"But, though in this manner we may obtain a satisfactory view of the upper half of the front of the globe, we shall not obtain any view of the conjunctival covering of the superior eye-lid. Eversion of this lid must be effected before its inner surface can be brought under examination, which cannot be done by simply elevating it, but may be by the following procedure:—The cilia occupying the central portion of the margin of the lid, are to be laid hold of between the thumb and fore-finger of the left hand, the back of the finger, at the same time, being placed upon the skin of the lid; then the cilia and ciliary margin being raised by the thumb, the substance of the lid is to be pushed downwards by the finger, and thus complete eversion of its conjunctival surface will often be readily produced. Sometimes, however, on account of the strong action of the orbicularis muscle, it will be more difficult to produce eversion, and it may be necessary, with the right hand, to employ a probe or some similar instrument to depress the upper and outer portion of the lid, while the thumb and fore-finger of the left hand are used to

raise the cilia and ciliary margin, as before pointed out. In this way, we may always succeed in obtaining a proper view of the conjunctival surface of the upper lid.

"In examining the eyes of children, however, it rarely happens that we can succeed in inducing them voluntarily to undergo the simple processes pointed out: if there be intolerance of light and much irritability, it is impossible, and we are compelled to resort to the forcible separation and eversion of the palpebræ. The only difference required in the mode of manipulating in this case, is to place the child's head upon or between the knees of the surgeon, while the rest of his body is supported by some other person, who is seated opposite, and who secures the hands, which are otherwise apt to be very much in the way. Generally, there is but little difficulty, when the child is properly secured, in obtaining a satisfactory view of the whole surface of the conjunctiva. The only exception to this statement is, where the palpebræ are, as is sometimes the case, enormously swollen, and the fissure between them is very small, as in cases of purulent ophthalmia, in which complaint, indeed, it is sometimes absolutely impossible to obtain an examination of any thing more than the conjunctival surface of the palpebræ, the tendency to eversion of the lids rendering this an easy task, however difficult it may be to expose the conjunctiva of the globe and cornea."

We have no doubt but that students will find this a very useful, as it is a cheap and convenient manual.

On Superstitions connected with the History and Practice of Medicine and Surgery. By THOMAS JOSEPH PETTIGREW, F.R.S. F.S.A. Surgeon to H.R.H. the Duchess of Kent, &c. &c. 8vo.

THIS is one of the most amusing books it has fallen to our lot lately to peruse; nor is the amusement unaccompanied by utility; for it is an attempt, in a certain degree, to account for apparently miraculous effects by a reference to natural causes. Mr. Pettigrew has brought together a variety of singular circumstances bearing upon the superstitions connected with the history and practice of his profession, whether

alchemical, astrological, sympathetical, or magical; and he has shewn that the effects recorded in these instances, of which he has, from an extensive course of reading, culled the most authentic and the most material, are to be ascribed to the power of the mind and the exercise of the passions over the natural functions of the body. This is a department of medicine to which we have often, in the course of our editorial labours, made reference as of high importance in the cure of diseases; and Mr. Pettigrew has brought together a variety of cases in which, by the operation of terror, joy, hope, grief, &c. various diseases have not only been removed, but actually excited.

Mr. P. sets out by assuming the truth of Southey's expression, that "Man is a dupeable animal. Quacks in medicine, quacks in religion, and quacks in politics, know this, and act upon that knowledge. There is scarcely any one who may not, like a trout, be taken by tickling." He endeavours to account for the celebrity of empirics, and the confidence so extensively reposed in them, partly from the conjectural and uncertain nature of medicine, and partly from the hope inspired by the patient under the continued expression of confidence of cure proclaimed by the charlatan. The mind is readily induced to believe in that which it desires, and seldom thinks, under such circumstances, of calmly and coolly considering the stability of opinions thus boldly avowed.

In the chapter devoted to alchemy, Mr. P. has satisfactorily shown that its origin is oriental; but that it is not to be, as Geber, Thomson, and others, have stated it, referred to so late a period as Arabian science: on the contrary it would appear, from Mr. P.'s acquaintance with Egyptian lore, that there are Enchorial MSS. in which numerous chemical formulæ have been found, and that therefore the art or science, whichever it may be termed, is to be traced back as far as the flourishing period of Egyptian history. When, indeed, we reflect upon the manufactures of Egypt, the making of glass, the manufacture of linen, the working of metals, and, above all, the use of mordants in the process of dyeing, it cannot but be obvious that the Egyptians possessed no inconsiderable acquaintance with chemistry.

Our author gives an account of the different stones of the alchymists, or such as they pretended to compound for the possession of rare and particular properties—the mineral stone, the vegetable stone, the magical or perspective stone, the angelical stone, the philosopher's stone; and has made several quotations from the writings of the most celebrated alchemists, which are worthy of perusal; and he concludes by noticing an extraordinary opinion, expressed so recently as the year 1800, by an eminent Göttingen professor, Dr. Christopher Girtanner, that, "in the 19th century the transmutation of metals will be generally known and practised. Every chemist and every artist will make gold; kitchen utensils will be of silver, and even gold, which will contribute more than any thing else to prolong life, poisoned at present by the oxys of copper, lead, and iron, which we daily swallow with our food."

The chapter on astrology contains much curious matter relating to talismans and the doctrine of signatures, which Mr. P. thinks may "be said to have taken their origin from belief that medicinal substances bore upon their external surfaces the properties or virtues they possessed, impressed upon them by planetary influence. The connection of the properties of substances with their colour is also an opinion of great antiquity: white was regarded as refrigerant, red as hot—hence cold and hot qualities were attributed to different medicines. This opinion led to serious errors in practice. Red flowers were given for disorders of the sanguiferous system, yellow ones for those of the biliary secretion, &c. We find that in small-pox red coverings were employed, with a view of bringing the pustules to the surface of the body. The bed-furniture and hangings were very commonly of a red colour,—red substances were to be looked upon by the patient. Burnt purple, pomegranate seeds, mulberries, or other red ingredients, were dissolved in their drink. In short, as Avicenna contended that red bodies moved the blood, everything of a red colour was employed in these cases. John of Gaddesden, physician to Edward II., directs his patients to be wrapped up in scarlet dresses; and he says that 'when the son of the renowned king of England (Edw. II.) lay sick of the

small-pox, I took care that everything around the bed should be of a red colour; which succeeded so completely that the Prince was restored to perfect health, without a vestige of a pustule remaining.' Wraxall, in his 'Memoirs,' says that the Emperor Francis I., when infected with the small-pox, was rolled up in a scarlet cloth, by order of his physician, so late as 1765, when he died. Kaempfer (History of Japan) says that 'when any of the emperor's children are attacked with the small-pox, not only the chamber and bed are covered with red hangings, but all persons who approach the sick prince must be clad in scarlet gowns.' Flannel dyed nine times in blue was held to be efficacious in the removal of glandular swellings." (Page 19.)

The supposed influence of the rising and setting of the stars, the eclipses of the sun and moon, the appearance of comets, &c. as influential in the production, as well as the relief, of diseases, is ably treated of; and Mr. P. seems disposed to agree with Dr. Balfour, and other writers on tropical diseases, as to the solar influence, of which, indeed, so many instances are on record, that it may fairly be entitled to the consideration of medical practitioners in general, but particularly of those who are engaged in tropical countries.

In tracing the progress of medicine and surgery from the earliest periods Mr. P. is led to observe: "As the possession of medical knowledge was considered to be received through the direct agency of heaven, it is natural to conceive the exercise of it to have originated with the priests. In early and superstitious ages, as already shown, diseases were regarded as inflictions of the divine vengeance; and means were therefore sought to appease the anger of the gods, and mitigate the celestial wrath. Appeals to the oracles, divination, and magic, henceforth became connected with medicine. Hippocrates was the first physician to relieve medicine from the trammels of superstition and the delusions of philosophy.

"Nothing could tend more to retard the progress of medicine, and paralyse all efforts for its improvement, than the opinion, once so generally entertained, of the celestial origin of disease, which, if admitted, appears necessarily to de-

mand divine interposition for its relief. Religion and medicine were both brought into contempt by the adoption of sacrifices and incantations, and the mercenary practices of the priests to insure intercession with the gods. Hippocrates resisted this folly and wickedness, and boldly declared that no disease whatever came from the gods, but owed its origin to its own natural and manifest cause. Even the learned Celsus, whose works are universally read and admired at the present day, whose writings are considered as forming a conspicuous portion of our standard medical literature, was not free of the prejudices of his time with regard to the origin of disease. In the preface to his work, '*De Re Medica*,' he expressly says, '*Morbos ad iram deorum immortalium relatos esse, et ab iisdem opem posse solitam*.' He, however, had too much good sense not to rely upon remedies as his curative agents, and, therefore, writes '*Morbi, non eloquentia sed remediis curantur*.'" --p. 29.

The connection of the priesthood with the practice of medicine is thus briefly stated:—

"There is reason to fear that the purposes of medicine were converted by the monks to the basest uses, and that the authority of the physician superadded to the terrors of the church, exercised over those in whom the mind was enfeebled by disease and incapable of exerting its power, were employed in the extortion of money and the indulgence of rapacity. Want of knowledge was supplied by mystery, and faith usurped the place of effectual prescription. Hence arose the employment of charms, amulets, relics, &c. The ignorance and the cupidity of the monks caused the Lateran Council, under the pontificate of Calistus II., A.D. 1123, to forbid the attendance of the priests and monks at the bedside of the sick, otherwise than as ministers of religion. Still, however, it was secretly followed, and Pope Innocent II., in a council at Rheims, A.D. 1131, enforced the decree prohibiting the monks frequenting schools of medicine, and directed them to confine their practice to the limits of their own monastery. Some, however, continued to pursue it, and some of the secular clergy practised it as generally as before, so that the decrees were found inefficient in the

accomplishment of their object; and a Lateran Council in A.D. 1139, threatened all who neglected its orders with the severest penalties and suspension from the exercise of all ecclesiastical functions; denouncing such practices as a neglect of the sacred objects of their profession in exchange for ungodly lucre. '*Ordinis sui propositum nullatenus attendentes, pro detestanda pecunia sanitatem pollicentes.*'

"When the priests ascertained that they could no longer confine the practice of medicine to themselves, it was stigmatized and denounced. At the Council of Tours, held in 1163 by Pope Alexander III., it was maintained that the devil, to seduce the priesthood from the duties of the altar, involved them in mundane occupations, which, under the plea of humanity, exposed them to constant and perilous temptations. They were accordingly prohibited the study of medicine, and that of the law, and every ecclesiastic who should infringe the decree was threatened with excommunication. In 1215 Pope Innocent III. fulminated an anathema specially directed against surgery, by ordaining, that as the church abhorred all cruelty or sanguinary practices, no priest should be permitted to follow surgery, or to perform any operations in which either instruments of steel or fire were employed; and that they should refuse their benediction to all those who professed and pursued it.

"Stringent as these measures were, they were found inadequate to effect the purpose intended, and it was only at length accomplished by a special bull procured from the Pope, which, by permitting physicians to marry, effectually divorced medicine from theology."—p. 34.

Mr. P. has also given a curious list of the principal Saints of the Romish Church, celebrated for the cure of different diseases, and enumerates some of the holy wells and fountains renowned for their miraculous powers.

Of talismans, amulets, and charms, our author gives an abundant supply of examples; and has usefully arranged them under the several diseases to which they have been, and continue in many cases still to be applied, in different parts of the world, and in our own country, specifying those which belong to particular countries. Our limits do not permit of an enumera-

tion of those; but the reader will find the most curious under the heads of epilepsy, chorea, madness, plague, ague, rickets, child-birth, and cramp.

The chapter "on the Influence of the Mind upon the Body," affords numerous examples of the operation of the passions upon the health of the individual, and may be referred to for well-authenticated instances of the change of colour of the hair by the depressing effects of terror or grief; also of immediate death from the same causes. Apoplexy also from joy. Mr. P. makes some judicious remarks on sympathy, and the influence it appears to exert, more particularly between the mind and certain organs of the body, than with others. The effects of mental emotions and passions upon the heart are well detailed, and deserve to be perused to a great extent. Among the effects produced by the imagination, reference is made to Dr. Haygarth's exposition of the metallic tractors of Perkins, and an interesting case is told of a man labouring under paralysis, cured by the application of a thermometer beneath the tongue of a patient by the celebrated Sir H. Davy; the patient believing himself to be thereby subjected to the operation of some powerful agent, which he had been assured would effect his cure.

Of the "Royal Gift of Healing," a practice, which, strange to say, continued from the time of Edward the Confessor to Queen Anne, a period embracing seven centuries, Mr. Pettigrew has given the most ample account extant, and submitted the substance of various proclamations, registers, &c. that he has met with in the State Paper Office and British Museum. These are very curious, and the history is arranged under the several reigns in which the practice was exercised. A small sum of money (gold medal) appears first to have been given by Edward I. but no particular coin for the purpose was struck until Charles II. of which Mr. P. has given an engraving, as well as of those adopted by James II., Queen Anne, and the Pretenders. Henry VII. was the first sovereign to establish a particular service of ceremony to be employed at the healings, and it was continued, with variations, until the reign of Queen Anne, in whose book of Common Prayer the service is printed.

Elizabeth practised it, but appears not to have been anxious to exercise her privilege. It flourished most in the time of Charles I. and II. Mr. P. gives the substance of eleven proclamations relating to it in the reign of Charles I., and there is a register of cases treated by Charles II. from 1662 to 1682, amounting to no less than 92,107 persons. The forms and ceremonies observed on these occasions are given, and the authorities by which they are supported, among which are to be found the names of some surgeons of deserved celebrity in their day. Somewhat akin to the royal touch, the reported cases of Valentin Greatrokes and Samuel Leverett are noticed, and the volume concludes with an interesting sketch of the sympathetical cures of Sir Kenelm Digby, upon which Mr. Pettigrew remarks:—

“It is not at all surprising that cures of the description alluded to should soon be looked upon as the result of magic, incantations, and other supernatural means; and that the professors of the sympathetic art, therefore, should have been anxious to account for the effects by natural causes. Such appears to have been Sir Kenelm Digby’s chief aim before the doctors of Montpellier; and similar reasonings upon the subject may be found in the writings of the supporters of the system already mentioned, who advocated the plan of treatment, and vouched for its efficacy. In this search for natural means to account for the phenomena obtained, the obvious one was overlooked; and the history I have given would be uninteresting but for the valuable practical lesson which these experiments have afforded. We owe to this folly the introduction of one of the first principles of surgery—one which, in this country, has done more to advance the science than any other beside—one which has saved a vast amount of human suffering, and preserved innumerable lives. The history of the doctrine of healing wounds by the powder of sympathy is the history of adhesion—the history of union by the first intention—a history which, until the time of John Hunter, was never fairly developed or distinctly comprehended.

“It has been well observed by the late Mr. John Bell, that ‘it is an old, but a becoming and modest thought, that in our profession we are but the

ministers of nature; and indeed the surgeon, still more than the physician, achieves nothing by his own immediate power, but does all his services by observing and managing the properties of the living body; where the living principle is so strong and active in every part that by that energy alone it regenerates any lost substance, or reunites in a more immediate way the more simple wounds.’ A wound, in general terms, may be defined to be a breach in the continuity of the soft parts of the body; and an incised wound is the most simple of its kind. These, it must be remembered, were of the description of wounds to which the sympathetical curers resorted, and their secret of cure is to be explained by the rest and quiet which the wounded parts were permitted to enjoy, in opposition to the ordinary treatment under the fallacious doctrine and practice of that day in digesting, mundifying, incarnating, &c. Surgeons in former times seem really, by their modes of treatment, to have tried how far it was possible to impede instead of to facilitate the processes of nature; and to those who are acquainted with modern surgery it almost appears miraculous that they ever should have been able to have produced union of any wound whatever. What is the mode of treatment now employed by the surgeon in the healing of a wound? To clear it from extraneous matter, to bring the edges into apposition, to keep them in contact by a proper bandage, to modify temperature, and to give rest. What is this but the mode of procedure on the part of the sympathetical curers? They washed the wound with water, kept it clean and undisturbed, and in a few days the union of parts—the process of adhesion—was perfected, and the cure was complete. The doctrine of adhesion, the exudation of lymph, the junction of old, or the formation of new vessels, and the consequent agglutination of parts, was then ill understood: subtle and, in many instances it must be admitted, ingenious reasons were resorted to, to account for the effects produced, and the true solution of the process was overlooked—the effect was apparent, but the cause was obscure.”—(P. 164.)

Numerous remarkable instances of adhesion of extensive surfaces, severed

parts, joints, &c. are given by our author, of whose work our readers will be able, from what we have noticed, to form a judgment. It is evidently the result of extensive professional and general reading, and, from the agreeable style in which it is written, likely to become popular, being equally adapted to amuse and instruct the historian, the antiquary, and the medical reader.

MEDICAL GAZETTE.

Friday, December 29, 1843.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

NEW CHARTER OF THE COLLEGE OF SURGEONS.

It may be in the recollection of our readers, that in the third number of the current volume (Oct. 20, 1843), we gave a copy of the Charter recently issued by Her Majesty Queen Victoria to the Royal College of Surgeons of London, and bearing date Sept. 14, 1843. That charter directs, that within three months from the issuing thereof, the Council of the College do prepare and set forth a Schedule, containing the names of not less than 250 of the existing members of the College, who shall have been selected by them as fit and proper persons to be promoted to the style, title, and dignity of Fellows of the said Royal College.

Within the last week, as in duty bound, the College have put forth such a Schedule of Fellows. It will doubtless give occasion to much discussion, to many heart-burnings, to jealousies, and a vast amount of envy, malice, and uncharitableness. Why was A selected and B passed over? Why was M taken and N left, will be the general topics of inquiry, as well in London as throughout the provinces, for some weeks to come.

We think the present a most favourable opportunity for offering a few re-

flections on the general character of the new charter, and some brief criticisms on its chief provisions. Most of our readers have, probably, cast their eyes over the charter, but the profusion of words in which lawyers delight to clothe their ideas, may have deterred many from a close investigation of its details.

The principal changes which the new charter effects in the constitution of the College, have reference—1. To the formation of a body of Fellows; 2. To the composition of the Council or governing body; 3. To the election, admission, and continuance in office, of the examining body. We shall, in the first instance, consider these several points in detail, and in the order here specified.

1. The charter directs that prior to the 14th Sept. 1844, a body of Fellows shall be formed out of the *existing* members of the College, consisting of not more than 300, (of whom 250 must be nominated before the 14th Dec. 1843) and that they be associated in one general diploma, to be enrolled in the High Court of Chancery, and, wonderful to say, without payment of fees. On all future occasions, however, the honour of the fellowship is to be coupled with certain conditions. These are three in number, viz :—1st, that the individual should have attained the age of 25 years; 2dly, that he should have passed such a special examination as the Council shall from time to time think fit, and by a bye-law direct; 3dly, that he should have complied with such rules as the Council shall in like manner, from time to time, deem expedient, and duly direct. The nature of these latter restrictions is not hinted at. Of the propriety of the first (touching age) no question can arise, but on the second condition declared by the new charter to be indispensable to the appointment of a Fellow, there will not only be a question, but unless

we grossly deceive ourselves, a most unanimous feeling of disapprobation among the whole profession, from Penzance to Berwick-upon-Tweed.

The Fellowship of the Royal College of Surgeons is an honour held out, and very properly held out, by the Queen, as a reward to those who have distinguished themselves either as authors, or as practitioners, or as discoverers, as men of general science, or of high character and reputation, or long standing in the profession. It is to the body of English surgeons what the order of the Bath is to the army. Is it fitting, is it decent, is it just, that men who have really thus distinguished themselves, should be subjected to a new ordeal in the shape of a second examination? Will they have the meanness or folly to submit to it? The proposed examination for the Fellowship must be either nominal or searching. If nominal, why retain the degrading ceremony? If searching, and calculated (as the recommenders of this strange proposition will probably tell us) to enhance the value of the diploma, then who will subject a character *already acquired* (for this is the hypothesis from which we start) to the risk of ruin?

In our apprehension this re-examination can serve no other purpose than to irritate, and give continual grounds for the suspicion of partiality. To obviate this latter objection (if the plan is to be persisted in), and if additional honour is really to be thereby acquired, let the wordy war take place in open court. Let a day be fixed, and the public be assembled, and let us hear Mr. Guthrie probing the surgical attainments, and the microscopical knowledge, of some grave general practitioner, who, at the age of 50, after thirty years of service, aspires to the dignity of a Fellow! The thing will not bear examination.

And the more we see of it, the less we like and embrace it.

Why did not the Council of the College take example from their brethren of Pall Mall East, where no such enormity was ever proposed or dreamt of? The penultimate clause of the charter contemplates evidently the interposition of Parliament to give additional force to the enactments of the royal charter. We hope that this opportunity will not be lost, and that either by petition to Parliament, or by application to the Queen in Council, this most obnoxious and hateful clause may be expunged, and *drummed out*, as it richly deserves.

To this master sin of the charter some minor ones must be added. For instance: power is given to the Council to appoint hereafter (that is, after Sept. 14, 1844) to the Fellowship, persons who have not previously been *members*. Let them be examined by all means; but surely it would have been better, following the precedent of the College of Physicians, to have made the Membership the sole door of admission to the Fellowship, and thus have avoided all pretext for a second examination.

2. We come now to the composition of the Council. This, the governing body of the College, is to be augmented from 21 (its present number) to 24. The existing members of the Council are to continue *for life*; but it is expressly provided that all future members of the Council may be relieved from duty when they shall be found no longer fit for it. It is obvious that this most wholesome regulation is intended to provide against the continuance of such men as Sir William Blizard in office, so soon as age and infirmities point out, in language not to be misunderstood, the propriety of retirement. It would probably have been too much to expect from human nature, that the present members of the

"It is a monster of so foul a mien,
That to be hated needs but to be seen."

Council should have voluntarily consented to such a sacrifice as the spirit of the new regulations evidently suggests. So we must let that pass, and be thankful that the Council have had so clear an understanding of what is good for their *successors*. We all remember how sensitive the Archbishop of Grenada was, when Gil Blas reminded *him* of the advance of years.

None but Fellows are eligible as members of the council, and not all of them; for the charter says that no Fellow practising midwifery or pharmacy, or who has been engaged in such disqualifying pursuits for five years preceding the day of election, shall be so eligible; and further, he must, in order to qualify for a seat at the council table, reside, and *bonâ fide* practise his profession of surgeon, within five miles from the Post Office in St. Martin's Le Grand. He cannot certainly live at Norwood or Hammer-smith, and we have our doubts whether Hampstead Heath be within the prescribed limits.

We know that the exclusion of the general practitioners from a seat in the council will give great dissatisfaction. It will be said, why cast this stigma upon men whose crime is, that while doing all that you do, they do yet more, viz. supply the physic which others only direct. We hold, however, that the distinction is a just and valid one; and that he who devotes himself to the study of disease exclusively takes a higher place than he who (if he does his duty) divides his time between the study of disease and regulating the details of practical pharmacy. Let him eschew the cares and superintendence of the shop, and in five years afterwards he becomes eligible to the council board. The remedy is at all times in his own hands. We consider the council quite right here.

The case, however, is different with

regard to practitioners in midwifery; and we are inclined to think that here is another blot in the new charter. Our reasons are these. The practice of midwifery is not an exclusive practice, like that of oculists and dentists. The purest accoucheurs that London now contains have had the education either of physicians or of surgeons. They know disease, and they know and treat it well. It is not likely that more than one or two such would ever be proposed for admission to the council; and we are quite prepared to say that the presence of one or two men, well skilled in the mysteries of midwifery, such as Mr. Blagden or Mr. Stone, would assist the deliberations, and promote the usefulness, of the council. Such men may be Fellows, and capable of assisting in the election of members of the council; but the charter declares them incapable of sitting at the council board themselves.

Again we say, why did not the council look to the practice of their friends in Pall Mall? Do they find any corresponding exclusiveness there? Do they not know that Sir Charles Clarke and Dr. Locock are among their most honoured counsellors; and that there is nothing to impede, but on the contrary every thing to encourage the belief, that in Sir Charles Clarke we behold an embryo president of the resuscitated college? We hope that the Queen may be induced to revise this clause of the charter before the seal of parliamentary authority be put to it. The Metropolitan University will afford a most convenient precedent (if one should be required) for the revisal of a faulty charter.

We come now to explain to our readers the machinery which the charter puts into operation for conducting the election of the council—that important body, to which is to be entrusted the entire government of the College, subject to no

control whatever, save that slight one to which we shall hereafter advert. It is obvious that these regulations may be very simple and very effective, but, on the other hand, they may be of such a nature, so involved, and so mixed up with essential conditions, but, at the same time, conditions so difficult of fulfilment, as to neutralize in a great degree the advantages which an elective council might be expected to draw in its train, compared with the system of *self election* which has hitherto prevailed. Whether the directions of the charter be of the simple or of the complex kind, is our next inquiry; but the details are tedious, and to enter upon them at present would exceed our usual limits. We will reserve them, therefore, for consideration next week, when the composition and mode of election of the examining body will also claim our attention. Some observations, too, may follow on certain apparent deficiencies in the charter, and on the principles which appear to have guided the Council in their selection of the 300 Senior Fellows of the College.

That, as a whole, the new charter is a prodigious step in the way of improvement cannot for a moment admit of doubt. It may not go so far as some even of the moderate class of reformers would wish, we are prepared to admit, but it contains the seeds of great good. It will promote a good understanding among the scattered members of the College, now a mere rope of sand, bound together by no common interest. It will raise the character of the British surgeon, high though it now so deservedly stands. The establishment of a select body of men, eminent for professional attainments, to be distinguished hereafter as Fellows of the Royal College of Surgeons, out of whom the governing and examining bodies of the College are ultimately to be formed, is of itself an

immense step in advance, and we gladly hail it as such. We cannot, however, shut our eyes to the glaring defects of the charter; and our voice, feeble though it may be, shall be raised to effect those improvements in it, which, without impairing the needful efficiency of professional government, will promote that good feeling which ought to exist among the members of a liberal profession, and encourage them to see in their new charter the harbinger of professional peace.

MIDDLESEX HOSPITAL.

THE election of an Assistant Physician took place yesterday (28th), when Dr. Seth Thompson proved the successful candidate. At the close of the poll the numbers were found to be,—

Dr. Seth Thompson . . .	368
Dr. Woodfall	242

Majority 126

Dr. Crawford, the former Assistant, was, as a matter of course, elected Physician. Dr. Thompson had not been a pupil of the Hospital, but had the support (we believe unanimous) of the medical officers.

WEST OF LONDON INSTITUTE FOR DISEASES OF THE EYE.

THE final and a very numerous meeting of this association, for approving and determining the constitution of this charity, was held on the 1st instant, at the residence of L. T. Flood, Esq., Belle Vue House, Chelsea, when a code of laws and bye-laws was adopted, and the following appointments confirmed:—

President.—The Earl of Denbigh.

Vice-Presidents.—The Earl of Carnarvon, the Earl of Errol, the Rev. Lord Augustus Fitzclarence, John Tollemache, Esq. M.P., J. H. Langston, Esq. M.P., the Rev. C. Kingsby, Rector of Chelsea, L. T. Flood, Esq., W. B. France, Esq., Thomas Edwards, Esq. LL.D. D.C.L., Benjamin Jones, Esq., E. J. Langley, Esq., Francis Chalmer, Esq., Otto Hamilton, Esq.

Medical Referees.—Dr. Hamilton Roe, Dr. J. A. Wilson, Anthony White, Esq., Thomas Callaway, Esq., Hale Thomson, Esq.

Consulting Surgeon.—John Scott, Esq.

Surgeons.—Mr. D. O. Edwards, Mr. A. B. Barnes.

Treasurer.—James Pitt, Esq.

Secretary.—Mr. A. Gall.

CASE OF

STRANGULATED INTESTINES,

FROM ROTATION OF THE SIGMOID FLEXURE

—WITH REMARKS.

BY JACOB BIGELOW, M.D.

THE Hon. Hugh S. Legare, Attorney-General of the United States, arrived in Boston on Friday, June 16th, and although fatigued by a hasty journey from Washington, was well enough to make calls on some friends in the evening. At 1 o'clock in the night he was seized with frequent abdominal pains, resembling those of colic, and called Dr. Thomas, of Washington, then lodging in the same hotel, to his assistance. During the remainder of the night, and the whole of the next day and night, he was affected with pains alternating with intervals of ease, without constitutional disturbance, and agreeing in character with those of previous attacks to which he had been liable for more than two years, the last occurring in March preceding. Various laxatives and enemata were resorted to, together with counter-irritants, but without removal of the constipation and pain.

Early on Sunday morning I was called to meet Dr. Thomas at Mr. L.'s lodgings at the Tremont House. I found him then suffering frequent paroxysms of pain, which he referred mostly to the lower abdomen, without distinction of side, but which sometimes mounted above the umbilicus. The pulse was at this time 69, the skin natural, with no tenderness on deep pressure of the abdomen in any part, no meteorism, no nausea. Opiates and other remedies were proposed to him, but declined, on the ground that lavatives and mechanical means had relieved his former attacks. During the morning two doses of *Ep om salt*, with infusion of senna and tincture of hyoscyamus, were given, with frequent enemata both aqueous and stimulating, without effect. The pains did not increase, but a troublesome degree of tenesmus made it necessary to suspend the enemata. Elastic tubes were passed through out the rectum, and water injected through them in the manner recommended by Dr. O'Brien, but they could not be carried into the sigmoid flexure. His strength meanwhile remained good, and his general condition stationary.

At 6 P.M. he was removed without difficulty to the house of a friend, where he was immediately put into a warm bath of 106 deg., from which he expressed great relief and satisfaction. He was then put to bed, and 60 drops of laudanum were administered in two doses. In about an hour, the relief not being perfect, 10 drops of Munn's elixir of opium were given, soon after which he fell

into a quiet sleep, and so remained for about three hours. Conditional directions were given for repeating the opiate, but it was not found necessary till near morning, when he took 20 drops of the elixir, and slept an hour or two more. On Monday morning at 5 o'clock I found him more comfortable than before, skin temperate, pulse 64, abdomen not tender but beginning to be tympanitic. Castor oil and senna, with hyoscyamus, were now given and retained, and enemata, fomentations and sinapisms, were resumed as before. The pain did not return with the same severity as before, but meteorism rapidly increased, with restlessness and tenderness on pressure. At 9 A.M., the pulse was 89, and before 12 it was 100. The face of things having become very serious, Dr. Thomas being absent from the city, I requested farther consultation, and Dr. Warren was called in. The abdomen was freely leeches and rubbed with croton oil. Various ineffectual attempts were made to overcome the obstruction of the intestines by the introduction of various tubes, by inflation of the rectum with a bellows, and by the tobacco injection administered twice. Under this last remedy he said he felt excited, was stronger but more agitated, and his pulse rose from 130 to 140, with increased force. Each injection contained half a drachm in infusion, and was retained nearly half an hour without narcotism or prostration. During the night the patient was restless, retaining his muscular strength in a considerable degree, and frequently getting up to the close stool in the belief of an approaching evacuation. There was never any vomiting nor nausea; the mind was clear, and the natural decisive tone of voice continued. He complained occasionally of a sense of burning at the epigastrium and upper abdomen. About half an hour before death, he got up without assistance, and on lying down asked urgently for water. On receiving it, he pushed it away, saying it was filled with ants. A white paper was then shown him, to which he applied the same remark. On being told it was an illusion of sight, he put forth his hand for the glass, but missed it, said a few words incoherently, leaned back, and expired quietly at half past 5.

Autopsy, seven hours after death.—

Externally the limbs were very rigid, and there was much lividity about the head and back. The abdomen was greatly distended. On laying it open the cavity seemed nearly filled by the sigmoid flexure of the large intestine, which extended across the abdomen into the right hypochondrium, and was in a state of such distension, that its external circumference was in one place fifteen inches. It had a dusky green colour, as if from commencing gangrene, but there seemed to be

no softening, nor diminution of the natural polish. The two extremities of the flexure connected with the colon above, and rectum below, were felt to be twisted together about the mesentery as an axis, into a firm cord or neck, about an inch in diameter; and on being carefully untwisted, the whole included portion was found to have made four turns, or two entire revolutions upon itself. There was no line of demarcation between the healthy and strangulated portions, nor was there any appearance externally of old disease about this part. The small intestine and the colon were moderately distended, but the rectum was rather contracted. The cavity of the peritoneum contained a small quantity of turbid reddish fluid, and in one place there was recent lymph upon the small intestine, but there were no other appearances of inflammation. Owing to the state of the body and the place of examination, the intestine was not opened, and no further dissection made.

Remarks.—Internal strangulation, we have reason to believe, is a fatal disease, except in rare instances in which a spontaneous restoration of the parts may under favourable circumstances have taken place. But the resources of art are for the most part unavailing, from our ignorance at the time of the nature and place of the lesion, and from the inaccessible situation of the part, unless by a dangerous operation, not to be justified under any diagnosis which can be seasonably made out. Among the various causes known to have occasioned strangulation, the rotation or twisting of the intestine is less common than some others. Yet in addition to the case which has now been described, two others have occurred in this city, under the observation of Drs. Homans and J. E. S. Jackson, the record of which I have seen, in which fatal strangulation occurred from the torsion or twisting of the sigmoid flexure.

Professor Rokitsansky, of Vienna, in a work on internal strangulations of the intestines, divides these lesions into three species. Of these, the second species consists in the rotation of one part round an axis most commonly formed by some other part. It appears to be the result of his experience that rotation round the mesentery as an axis can happen only to the small intestine. But it appears from the case above detailed, and the two others above alluded to, that the large intestine is capable of undergoing this rotation, and from its anatomical position, no part seems more exposed to this change of situation than the sigmoid flexure.

From remarks made by Mr. Legare during his illness, it is believed that in some of his former attacks of colic and constipation, relief was obtained by the introduction of the elastic tube beyond the seat of the stricture. This happy result is to be ascribed to the

spasmodic character of the obstruction then existing. But when the intestine is rendered impervious by mechanical strangulation, it is evident that an instrument would sooner perforate the coats of the canal, than admit of being forced through the closed and tortuous passage. In the present case, tubes, some of which were two feet in length, were introduced into the rectum, and water injected through them continually to facilitate their progress. But the more flexible tubes were bent into a coil in the rectum, and the more rigid ones were irresistibly stopped at the sigmoid flexure, and could not be further forced without danger of perforating the intestine, an accident well known to have followed injudicious and violent efforts.—*Boston Med. and Surg. Journ.*

CASE OF

ABSCESS THROUGH THE LUMBAR REGION OF THE BACK;

DISCHARGE OF TWENTY STONES.

By A. H. PERKINS, M.D.

I SEND you enclosed, two (of twenty) stones discharged by an abscess through the lumbar region of the back.

The patient is a man of apparently good constitution, and has enjoyed moderate health for many years. About ten years since, he says, he had frequent pains in his back, and much acidity of stomach, which were removed by treatment.

In February 1842, I saw him, in company with Dr. D. Tubb, of Matthews County. A few months before a swelling had commenced in his back, just below the kidney of the left side, and continued to increase until this time. Punctices, &c. had been used, and now a fluid was perceptible to the touch. An abscess-lancet was introduced to the depth of an inch through the swollen part, and a considerable quantity of serous blood escaped, and continued to escape for several days. The poultices were reapplied, but owing to irregularity of treatment, a sinus of an unhealthy character was formed, which was cured with port wine injections, caustic, &c. No disease of the kidney was suspected. The digestion was good, urine tolerably clear, and the gentleman enabled to attend to his office of Sheriff throughout the whole period, and it was thought advisable to close the wound. It continued, however, tender, with occasional pain in the part, until December following, when it commenced rising again. Broke in March following, and discharged the stones above mentioned. The pain in the back was intermittent throughout the whole period, not much increased by pressure; the constitutional symptoms very slight; and the urine not more sedimentous

than occurs in slight febrile affections, and not constant in that situation.

The place is now open, discharging pus with a grisly substance protruding from it. I advised the application of caustic; constitutional treatment was refused, the patient being a Thompsonian.—*Philadelphia Medical Examiner*.

STATISTICS OF THE ROYAL COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

IN reading your excellent article on the Statistics of the College of Physicians, in the GAZETTE of to-day (Dec. 15), I observe the following.

"We do not clearly understand the cause of this sudden fondness in favour of the Extra Urban License of the College of Physicians. It seems to denote a wish to nestle under the College wings, but we suspect there is something at the bottom of this new-born zeal, more than we have been able to fathom. It is hardly worth while to inquire, for the class of Extra Licentiates is doomed to a speedy decay."

The foregoing may be regarded as an intimation that the Extra Licentiates are to be raised to the rank of Licentiates; without informing us how it is to fare with the present Licentiates. Are they to be raised to the rank of Fellows? or are they to remain a degraded class, in statu quo? Many of these gentlemen are of high standing and respectability in the profession, having passed the same, and consequently as good an examination as the "Fellows," and to them it would, indeed, be an act of injustice to thrust upon them a body of men, however respectable, who had not passed the same examination, and possessed the same qualifications.

To be consistent, the College must either raise the present Licentiates to the rank of Fellows, or allow the Extra Urbans to remain, as they are at present, a distinct grade.

I am sir,

Your obedient servant,

A LICENTiate.

MUNIFICENT SALARY.

To the Editor of the Medical Gazette.

SIR,

I HAVE just seen on the fly-leaf of your last GAZETTE, a repetition of the advertisement for a "house-surgeon and apothecary to the Taunton and Somerset Hospital," by which it appears that "he must be a member of the College of Surgeons, and a licensed apothecary. He will be required to reside in the hospital, and restricted from practising

out of it. Salary £50 per annum, with board at the matron's table," &c.

I am glad to find that it has been necessary to repeat this advertisement, inasmuch as it evinces that no gentleman, so educated and qualified, can be found who will disgrace himself and the profession, by acceding to the terms and wages of a servant out of livery.

I am, sir,

Your obedient servant,

J. C. BADELEY, M.D.

Chelmsford, Dec. 9, 1843.

ON PNEUMO-THORAX :

AN ESSAY,

*Read (in part) at the Physical Society of
Guy's Hospital,*

By H. M. HUGHES, M.D.

One of the Assistant Physicians to the Hospital.

COULD a well-informed physician of the last century again appear upon the stage of active life, and investigate the progress made in pathology since his death, I scarcely know any complaint in which he would find a greater change of opinion to have occurred among well educated medical men, than that which forms the subject of the following observations. Should there be any professor of the healing art now living who entertains a doubt as to the advantages derived from what is commonly called physical diagnosis, combined with the active pursuit of morbid anatomy, in enabling the medical practitioner to arrive at a correct appreciation of certain symptoms, or the medical philosopher at just conclusions as to the nature and origin of certain diseases of the chest, I know not any complaint to which his attention might be directed with greater confidence than to pneumo-thorax. If such an individual will but compare the chapter of the great discoverer of the uses of auscultation, and almost equally great morbid anatomist, upon this subject, with the writings* of those who preceded him, I think he can no longer continue to feel or to express any doubt upon the matter.

Previously to the investigations of Laennec, pneumo-thorax was supposed to arise almost universally either from a secretion of the pleura itself, or from the decomposition of the fluid of empyema, or a suppurating lung. At the present time, all morbid anatomists

agree that the gas, in a vast majority of instances, is introduced from without; all assent to the proposition that the secretion of elastic fluid by the pleura and other serous membranes is, to say the least, exceedingly rare; and some, while they deny not the possibility of such an occurrence, express considerable doubt if it ever occurs. "Nothing," says Andral, "is more uncommon than pneumo-thorax produced by exhalation from the pleura*." In all the cases he had seen, he says in one part of his work, "the existence of the gas in the pleura was the result of the existence of a pulmonary fistula," connecting the cavity of the serous membrane with the bronchial tubes. He subsequently, however, relates a case (No. 21) "presenting the very rare instance of an effusion of gas into the pleura without there being any communication between the cavity of this membrane and the exterior." Laennec recognised the decomposition of albuminous fluids as a cause of pneumo-thorax, and others of the French school of pathologists probably still maintain the correctness of this opinion. But as far as I have been able to ascertain by a careful perusal of his cases, Laennec appears to have retained it, and even to have considered this origin of the complaint "pretty frequent," simply because in the cases examined after death an opening communicating with the external air was not always discovered. His want of success in attaining this object I cannot but attribute in great measure to his neglect of the only certain mode of arriving at it; viz. the careful inflation of the lungs under water by the aid of the blow-pipe. There are, I believe, but few recent English writers who recognise the decomposition of effused fluids, and of blood, as a cause of pneumo-thorax. I think it indeed doubtful if any British pathologist would, at the present day, be willing to admit, or disposed to maintain, that in the living body such an amount of

* I have endeavoured unsuccessfully, both in Paris and London, to obtain the essay of Itard on Pneumo-thorax.

* Clinique Medicale, translated by Spillan.

decomposition of the fluids effused into serous membranes as to give rise to the evolution of gas, can take place without the access of the external air. "It may be laid down as proved," says Dr. Houghton, "that where pneumo-thorax exists the air has been introduced from without; for cases of an opposite description are so rare that they must be considered as exceptions to the rule*." There is much truth and candour in the following observation of the judicious Chomel. "Le presence d'une certaine quantité de gaz et de gaz inodore chez tous les sujets qui ont succombé à cette espèce de pleurisie, (viz. from the opening of a tuberculous abscess) l'absence presque constante de ces gaz chez tous ceux qui succombent à une pleurisie ordinaire doivent porter à croire que dans les cas où la communication du tubercle avec les bronches n'a pas été évidente, elle a pu néanmoins exister. Les médecins accoutumés aux recherches d'anatomie pathologique savent combien elles offrent quelquefois et particulièrement dans des cas de ce genre, je ne dirai pas seulement de difficulté mais d'obscurité et d'incertitude."†

But though the views of physicians of the present day as to the nature of pneumo-thorax are very different from those current half a century ago, and though the very general belief exists among them that the gas is almost universally introduced from without, I have been a good deal surprised in my investigations upon the subject, to observe how various are the opinions of even recent writers upon some points connected with the disease, and how different have been the conclusions arrived at by some pathologists from those which have been deduced from the observations of others. Thus, the late Dr. Andrew Duncan‡ believed that "pneumo-thorax was commonly a consequence of empyema, or was preceded by it," while Dr. Houghton expresses an opinion that in a great majority of cases it proceeds from a tubercular cavity bursting into the sac of the pleura. Laennec, again, says that he never saw a patient affected with pneumo-thorax who was not confined to bed (alité). Louis, that life, in his experience, has not been protracted beyond thirty-six days, which he evidently regards as a long period. And Andral asserts§ "that it generally proves fatal in a very short time, though in some cases the patient has lingered as long as thirty days." How very different has been the experience of many on this side the channel!

Dr. Stokes records the case of a gentle-

man who not only lived for five months after it was proved that he was suffering from this disease, but who improved in health, and increased in flesh during that period, and stated that the only inconvenience to which he was subjected by his complaint was the splashing of the fluid, which occurred while taking exercise on horseback. He also mentions the case of a man who, when suffering more than usual from the accumulation of purulent fluid from the pleura, was accustomed to lie down upon his back and tilt his body by making a purchase with his feet against a wall, and who, by a copious expectoration thereby induced, was enabled to relieve himself from a portion of his inconvenient load. Dr. Houghton had a patient who not merely lived a year after the disease was known to exist, but who, notwithstanding the repeated cautions of his physician, would persist in following his employment of bricklaying, and was actually for some time engaged upon a wall near the hospital in which he had been confined. Some who now hear me, or who may subsequently peruse this paper, will probably call to mind the case of a man who, about eight years ago, was in Naaman's Ward of this hospital, who was evidently proud of the splashing noise he could voluntarily produce by shaking his body, and who was delighted by an opportunity of exhibiting to a passing pupil, in his progress down the ward, the phenomena of "Hippocratic succussion." This man, after having been cured of the catarrh for which he was admitted, spontaneously left the hospital, as he felt quite well enough to follow his ordinary occupation. He has not since been heard of at the hospital. Dr. Barlow, in the 4th vol. of the Guy's Hospital Reports, records the case of a young woman who, though weak and delicate during the winter, improved in health, and actually got fat, for three successive summers, and who lived for at least three years with the well-marked signs of pneumo-thorax. This is at once a very remarkable illustration of the very small portion of respirable lung with which life may be supported, and, I believe, the most protracted case of indubitable pneumo-thorax that has yet been recorded.

Seeing, then, that the experience of individuals in this affection has been so different, and has led to conclusions so various, I have thought that a brief general history of the complaint, founded upon cases already published, and especially upon those of which notes have been preserved in the hospital, together with the results of my own personal observation, would not be uninteresting to the members of this Society, and might not be altogether unacceptable to other members of the profession.

"In every case," says a late writer, "in which air, whatever its chemical constitution

§ Pathological Anatomy, translated by Townsend and West.

may be, is contained between the pleura pulmonalis and pleura costalis, the disease is pneumo-thorax." According to this definition, which is, strictly speaking, correct, whenever, in the operation of paracentesis thoracis, a few bubbles of air pass into the cavity of the pleura, or when an empyema bursts externally, and air supplies the place of a small portion of the fluid which escapes, the case becomes complicated with pneumo-thorax. Such, however, is not, I consider, in the present day, the ordinary acceptation of the term. Such cases are not generally regarded by either British or foreign pathologists as examples of pneumo-thorax, as it is scarcely credible that Laennec should not have seen persons thus affected who were not confined to bed, or that Louis and Andral should not have witnessed individuals who had suffered from empyema with external fistula, or "open empyema," for months, and even years together. Upon this form of complaint, then, it is not my intention to dilate; such cases are more properly ranged under the term empyema. But as two instances have fallen under my notice, the histories of which were somewhat unusual, and involve considerations of great practical importance, I may, perhaps, be allowed briefly to refer to them.

CASE I.—A woman, aged about 28, came under my care four years ago, as a patient of the Surrey Dispensary. She had the general symptoms of phthisis, hectic, nocturnal perspirations, cough, copious expectoration, great emaciation, debility, and a rapid feeble pulse, and also a discharge from two sinuses in the thoracic parietes on the right side, of which one was below the mamma; the other passed through a portion of the gland. The discharge from one or both of these sinuses alternated with the expectoration; when the one decreased the other increased in proportion. When the discharge from the side was profuse there was little or no expectoration; when the former ceased, or its passage became obstructed, the latter was very abundant. The side was contracted, dull on percussion, and destitute of healthy respiratory murmur. Over a small space below the clavicle alone was heard a little coarse and rough respiration. Tubular breathing and bronchophony existed posteriorly, and fistulous breathing anteriorly and inferiorly. The history which the patient gave of her complaint was, that after her confinement several months ago, she had a "bad breast," which was poulticed; suppurated, and burst spontaneously; and that very soon after this event she observed air proceed from the opening of the abscess; that she began to cough and expectorate, and had continued to do so, with gradually increasing debility, up to the time I saw her. She was ordered tonics and sedatives, and to continue the poultices

to the sinuses. After several weeks, the discharge diminished, and the cough decreased, though her general health improved very slowly, and her debility remained nearly as great as upon my first visit. For the purpose of improving her general health, and that she might not be exposed to the harsh usage of a drunken and dissolute husband, she was now advised to go into the country, and was not seen by me for more than two years. After the lapse of about six and twenty months, a person applied to me at the Dispensary for some trifling stomach complaint. She was stout, sleek, and ruddy, and looked in such really rude health, that I was surprised she required the aid of the doctor. After I had made some inquiry, she said, "You do not recollect me, sir; I am the person you attended in Crosby Row. My husband died, and I have got another, sir, and have had a child, sir, since you saw me." Even after this statement, I could scarcely recognise in her the pallid, emaciated, sickly thing, I had formerly attended. She, however, told me that the discharge, cough, and expectoration, had ceased, and the wound had healed, but that she was occasionally troubled with flying pains in the side, and shortness of breath. I much regret that my engagements at the time prevented me instituting an examination of her chest, and that, being unacquainted with her address, I have since had no opportunity of doing so.

CASE II.—Anne Johnson, aged 36, was admitted into Guy's Hospital, Sept. 21, 1841, with cough, expectoration, and discharge from the right side, immediately below the mamma, with all of which she had been troubled for ten months. The history of her complaint, and the symptoms and local signs of her disease, were so similar to those related of the last person, that I consider it quite unnecessary to detail them. She was occasionally attended by Dr. Barlow and Mr. Cock conjointly with myself. Mr. Cock, while adopting means to ensure a free opening for the discharge of matter, and thereby to favour the collapse and contraction of the side, was able to pass an elastic catheter four or five inches into the chest, and he was inclined to the belief that the cavity from which the discharge proceeded was situated, principally at least, in the lung itself. She continued in the hospital till March 10, 1842, and though little or no progress was made in the cure of her complaint, she left with her general health in no degree diminished by the long-continued drain to which she had been subjected.

Doubts may, I am aware, exist, as to the origin of the disease in these two cases, and a difficulty may be felt in deciding whether the empyema or the mammary abscess was the primary affection; as the information necessary for a correct determination of the question

was, in both cases, derived from the patients themselves. After repeated examination in each case, I was myself led to believe that the mammary abscess certainly preceded the affection of the pleura. The late Dr. Andrew Duncan* mentions a case in which abscesses of the parietes of the chest became emphysematous in consequence of communication with the bronchial tubes, and in which the fluid contents of the abscesses were expectorated through those channels. Thus it appears that though matter may always have a tendency to make its way to the surface, it does not necessarily take the most direct course: and it is clear that even in mammary abscess, as to the desirableness of opening which great diversity of opinion exists, "the line of road may sometimes be marked out" by the surgeon with great advantage to the patient.

Causes of pneumo-thorax. — Pneumo-thorax may arise from causes exterior to the lung, or from disease or lesion of the organ itself. Among the former set of causes may be mentioned,—

1. The fluid of an empyema bursting into a bronchial tube, and the inhalation of air through the opening by which the fluid escaped.

2. Laceration of the pleura costalis, combined with emphysema of the cellular membrane, arising from injury to, or ulceration of, the larynx or trachea.

3. A fistulous communication between some portion of the alimentary canal and the sac of the pleura, and perhaps—

4. Gangrene of the pleura connected with necrosis of a rib.

5. The decomposition of blood, and other albuminous fluids effused into the pleura, and,—

6. The gaseous exhalation of the pleura itself.

Of these the first is by far the most common cause of pneumo-thorax. Of the second I am only acquainted with one example; a case related by Dr. O'Brien in the *Edinburgh Medical and Surgical Journal*, Vol. 18. Of the third I have also met with but one illustration, in a case related by Dr. Stokes. Of the remaining causes in this division it may, I believe, at least be said, in Scottish phrase, that they are "not proven." Of the last, indeed, viz. the gaseous exhalation from the pleura itself, several supposed examples have occurred, during the progress of pneumonia, to some Irish physicians of high repute. I have not myself had an opportunity of witnessing any cases of this kind. I do not, therefore, feel myself qualified to offer an opinion as to the origin of the remarkable phenomena that have been observed; but, from a striking instance mentioned by Dr. Hudson, in the very valuable paper "on typhoid pneumonia," published

by him in the *Dublin Journal*, in the year 1835, I think it sufficiently evident that the phenomena observed could not have arisen from pneumo-thorax. The patient, for many hours before her death, had a remarkably tympanitic resonance on percussion, and absence of respiration, similar to that existing in, and supposed to be pathognomonic of, the disease under consideration, on the side, and in the part previously affording distinct indications of a consolidated lung. She was seen by her physician six hours before her death, and the presence of the remarkable resonance was at that time verified; but upon inspection of the body after that event, not only was there no air in the pleura, but the lung was found consolidated throughout, and the pleura costalis and pleura pulmonalis were *universally and closely adherent by firm lymph of considerable standing*. I think this case is so well and so distinctly related—the facts are so precise, definite, and unanswerable—as entirely to settle the question of tympanitic resonance and absence of respiration necessarily indicating the presence of gas in the pleura. The hypothesis which Dr. Hudson, in the same paper, very modestly enunciates as a possible explanation of the phenomena observed, viz. that the tensely consolidated lung acts as a conductor to the sound produced by the vibration of the air contained in a large bronchial tube, which it surrounds (an opinion advocated by Dr. C. J. B. Williams, and others), appears to me, upon common acoustic principles, to be equally untenable. In the absence of farther and necessary observation, flatulency of the stomach and bowels seems to be the most probable source from which an explanation of the curious and interesting facts is to be derived.

The causes of pneumo-thorax connected with disease, or lesion of the lung itself, are the following:—

- 1st. The opening of a tubercular excavation into the pleura.

- 2d. The escape into the pleura of air through softened tubercular matter, communicating with a bronchial tube, but not connected with an excavation.

- 3d. Gangrene of the lung and pleura.

- 4th. Laceration of the lung and pleura from external injury.

- 5th. The bursting of an enlarged pulmonary vesicle from the violence of coughing, in emphysema of the lung.

Of all causes, probably the first of these gives rise the most frequently to pneumo-thorax. It may, however, admit of reasonable doubt whether, in all the cases in which a tubercular excavation is found to communicate with the pleura, the fluid contents of the vomica have passed into the serous membrane, and thus given rise to pleuritis and emphysema: or whether the

* *Edin. Med. Chir. Trans.* Vol. i. p. 438.

fluid of a previously existing pleuritic effusion may not rather have, by its pressure, caused ulceration of the intervening tissues, and thus, by being partially evacuated, have opened a passage for the admission of air—whether, in fact, the coexistence of a vomica, pneumo-thorax, and empyema, necessarily proves that softened tubercular matter has escaped into the pleural cavity.

The second cause above mentioned is probably the next in frequency to that already noticed. The accidental rupture or ulceration of the pleura over tubercles, and the consequent escape of air, sometimes occurs in the earlier periods of phthisis, even before much softening has taken place, and when very few tubercles are deposited in the lung. A curious case* of this sort is related by Dr. Townsend, in which only a "single nidus," containing six or seven tubercles, could be discovered in any part of the lung. Andral speaks of a similar example, in which, at most, six or seven tubercles were found in the lung, one of which, as large as a small nut, was unfortunately situated close to the pleura. Two cases, though of a much less remarkable character, will be hereafter mentioned. Pneumo-thorax from gangrene of the lung is a rare affection, and though a few cases have been stated to arise from external violence, it is remarkable, considering how comparatively frequent are wounds of the lung from pointed instruments or fractured ribs, and consequent emphysema of the cellular membrane, how uncommon is the complication of pneumo-thorax, as indicated by its ordinary symptoms and physical signs. The only case of pneumo-thorax arising from a rupture of the cells of an emphysematous lung, with which I am acquainted, is mentioned by the late Dr. Thomas Davies†.

In the following table is stated the apparent cause of pneumothorax in sixty-two cases, of which I have either examined the histories as related by others, or which I have myself witnessed. It may be necessary to state that I have included therein only one case which has not been examined after death; and none which have been barely alluded to, or of which the particulars have not been recorded. I have not, therefore, inserted the singular case of Dr. T. Davies, arising from rupture of the pleura and pulmonary cells in emphysema, or others arising from laceration of the lung. I may also observe, that when phthisis, and especially phthisical cavities, have coexisted with air in the pleura, I have assumed, in the absence of other obvious cause, that the tubercular disease has given rise to lesion of the pleura, allowing the admission of air, even though the aperture

through which it had passed, had not been detected after death, especially as in some cases scarcely any attempt has been made to discover the opening, and though, as I have already hinted, it may perhaps be doubted whether in some others the vomica has really broken into the pleural sac, or an empyema burst into a tubercular excavation.

Causes of pneumo-thorax in 62 cases arising independently of external violence:—

Phthisis	47
Of these, fluid effusion is also stated to have existed in the pleura in	27
— fluid effusion is not stated to have existed in	17
— fluid effusion is stated not to have existed in	3
Empyema	8
Gangrene of the lung and pleura	4
Fistulous communication with the colon through the liver and diaphragm (from hydatids)	1

Symptoms of pneumothorax.—The escape of air into the pleura is said to be indicated by severe and suddenly supervening dyspnoea, pallor of the face, clamminess of the surface, coldness of the extremities, a frequent and fluttering pulse, and other symptoms of general collapse, together with pain of the affected side, and sometimes a sensation of fluid passing into the sac of the pleura. Of the seven cases related by Louis, the general symptoms occurred in all, and in six of the seven they were accompanied with local pain, while in one only was the sensation of the passage of the fluid experienced. It cannot indeed be denied that the accession of this complaint is in some cases marked by the sudden supervention of such symptoms; but it is assuredly likewise true that pneumo-thorax frequently occurs without them. When, indeed, a person previously suffering from phthisis, or even what is popularly termed "a delicate state of the lungs," is suddenly subjected to such a train of symptoms, and when they are accompanied, or followed by the signs afterwards enumerated, it may be pretty confidently asserted that air has escaped into the pleura. But from the observations of others, as well as myself, I may assert with equal confidence that pneumo-thorax may exist without any circumstances having been observed by the patient or his friends by which the exact period of its formation could be indicated. In support of this opinion, I may refer to cases by Drs. Stokes, Townsend, Houghton, Barlow, and others, as well as to some of those to be subsequently detailed in this paper.

The general symptoms of pneumo-thorax,

* Transactions of the Associated Physicians and Surgeons, Dublin, Vol. 5.

† MED. GAZETTE, Vol. 5.

independently of those supposed to mark the period of its supervention, are neither very remarkable nor characteristic. They are hurried respiration, decubitus on the affected side, pallor of the face, an anxious expression of countenance, a small, feeble, and frequent pulse, cough, with more or less expectoration, and sometimes febrile excitement and pain of the side. Even if these symptoms were constant, they possess nothing of a distinctive character. But they are not collectively always present. Thus, though the favourite position of the patient is usually one considerably inclined to the diseased side, some lie indifferently upon either side, or upon the back, without increased distress or inconvenience. Though the cough is sometimes pretty frequent, it is occasionally so trifling and rare as altogether to escape the notice of the observer; and if previously troublesome, it sometimes decreases very perceptibly to the patient after the occurrence of the accident. Pleuritis and its accompanying pain and fever are sometimes occasioned by the escape of gas and tubercular matter, but it is either not a necessary result of the lesion, or is occasionally so slight as to escape observation.

But if the general symptoms are not distinctive, the physical signs are such as are not easily mistaken. They are, tympanitic resonance on percussion, and absence of respiration; imperfect elevation, or immobility of the ribs, and more or less enlargement, or altered configuration of one side of the chest; partial displacement of the heart and diaphragm; amphoric breathing, metallic tinkling, metallic resonance of the voice, and cough; and, if fluid likewise exist in the pleural cavity, Hippocratic succussion.

I do not think it necessary or desirable that each of these symptoms should be separately examined and discussed; but I feel that I am called upon, or at least that I am fairly entitled, without a charge of prolixity, briefly to state the result of my own experience in reference to several of them.

Tympanitic resonance on percussion, and absence of respiration, have been by some regarded as almost pathognomonic of pneumo-thorax. This opinion is certainly founded upon insufficient evidence, as I have myself seen more than one case in which the side, as a whole, was dull rather than resonant upon percussion, and in which, even locally, it was not more resonant than natural. I also several times examined one patient in whom the whole of the side was obviously, decidedly, and incontrovertibly, dull on percussion, but in whom the other indications of the presence of pneumo-thorax were at the same time well marked during life, and in whom the existence of the disease was verified by inspection of the body after death. I have also seen tympanitic resonance on percussion,

and absence of respiration, in nearly the whole of one side, produced by the co-existence of a firm, airless, and contracted lung, and of a stomach largely distended with gas passing high above its ordinary level; and I feel assured that one at least of my colleagues at the hospital can bear testimony to the doubts and difficulties which may arise from this cause. The cases also of pneumonia, accompanied with tympanitic resonance, such as have been related by others, but, as I have previously acknowledged, have never been witnessed by myself, might likewise be advanced against the pathognomonic character of these signs. Occasionally also the lung is so bound down to the diaphragm and pleura costalis by old pleuritic adhesions as not to be removed by the subsequent effusion, and thus to admit, at some parts, of a little hoarse and indistinct respiratory murmur, which might render the existence of the complaint doubtful to those by whom *absence of respiration* is considered as its almost necessary accompaniment.

Insensibility of the side, or imperfect elevation of the ribs, is almost constantly present; but enlargement of the side, and partial dislocation of the heart and diaphragm, are far from being universal attendants upon pneumo-thorax. In some cases the shape and size of the affected side of the chest is unchanged, in others it is misshapen, contracted, and smaller than the opposite side, in consequence of old pleurisy.

Amphoric breathing, metallic tinkling, metallic resonance of the cough and voice.

—The whole of these signs depend upon the shape and size of the aperture in the pleura, and the size and lining of the cavity into which it leads. Arising from the reverberation or echo of the vibrations producing the common sounds of tubular breathing, of the cough and the voice, they are necessarily modified by the circumstances which give rise to that reverberation, and become more or less distinct, and even disappear altogether, and re-appear, according as the cavity is large or small, or is more or less occupied by liquid effusion. Thus the common fistulous breathing which is present when a cavity is of small or of moderate size, acquires a metallic ringing character when the cavity is large. When a portion of mucus or of membrane partially obstructs the opening, or when a drop of bronchial secretions falls into the fluid effused, or again when the opening into the pleura is situated below the level of the fluid, and bubbles of air pass through it, and burst upon its surface, the curious phenomena of metallic tinkling are produced—a sound which, in its most perfect form, more nearly approaches to that caused by shaking a pin in a large bottle or decanter, than any other with which I

am acquainted. When both the cavity and the opening are large, the sound resembles that produced by blowing into a large wide-mouthed bottle, and constitutes amphoric breathing—"bourdonnement amphorique," or "atricular buzzing."

For the production of *Hippocratic succussion*, a large cavity and the presence of both air and fluid is necessary. It is the noise caused by the splashing of fluid in a confined space. It is heard only when the fluid exists in a quantity, considerable indeed, but not so large as nearly to fill the cavity and thereby exclude a necessary amount of air—little sound is produced by shaking a bottle which contains either a few drops only of fluid, or so much as nearly to reach the cork. Hippocratic succussion may be generally easily elicited in the following way, which, I think, causes less inconvenience to the patient than either getting an assistant to shake him by the shoulders, as originally recommended, or requesting the invalid to give a twist or jerk to his own body, as recently advised. Press the ear firmly against the part of a chest in which the sound is most distinct; grasp the body of the patient with one arm, then smartly swing both body and head to and fro, and suddenly stop the motion. By these means, undulations are caused in the fluid without violent agitation, and generally, if not too long continued, without any distress, fatigue, or inconvenience to the invalid.

Theory of the difference of Symptoms and Physical Signs of Pneumo-thorax.

—I am induced to say a few words upon this subject, as it has appeared to me that the great variety in the continuance and severity of the symptoms, obviously in a great measure dependent upon the different physical conditions under which pneumo-thorax occurs, has not been hitherto sufficiently noticed, and that a more strict attention to, and just appreciation of, the diversified conditions of the organs in which it takes place, are necessary to a correct view of its pathological history.

If, between a bronchial tube and the sac of the pleura, a communication were made through which the external air was freely admitted into its cavity, and if the lung and pleura were both free from disease, the first effect of the operation would be a certain amount of collapse of the lung—the result of its proper elasticity. If, then, the ingress and egress of air to and from the pleura continued free, the lung, in consequence of the greater facility with which the air passed into the pleura, would be, as a whole, but little expanded upon inspiration, and that portion of it to which the injured bronchial tube was distributed, would not be expanded at all. Less blood would be sent to the

organ, its functional activity would decrease, its size would be gradually diminished, and air accumulating in the pleura would slowly occupy the space. If, on the contrary, while the ingress of air to the pleura took place with facility, its egress therefrom were prevented, or effected with difficulty, in consequence of some obstruction—if, at each inspiration, air passed into the sac of the serous membrane, and its escape during expiration were, in great measure, prevented either by the situation or form of the aperture—it is evident that the complete collapse of the lung would be greatly accelerated, and that the distress experienced by the patient would *ceteris paribus* be proportionably great. If, however, a great part of the lung were already so diseased as not to admit of expansion—if a considerable portion were occupied by cavities, or consolidated, in consequence of pneumonia or tubercular deposit—or if it were in some parts already closely adherent to the diaphragm or pleura costalis, through former pleuritis—then it is clear that not only would there be less lung capable of being collapsed, and therefore that, other circumstances being equal, the alteration in the circulation and aeration of the blood would be necessarily less extensive, but also that the collapse of that portion which was still crepitant and expansible would be in some measure prevented by the diseased parts by which it was surrounded. The air escaping, under such circumstances, into the space of the pleura which was not adherent, would be limited in quantity; the extent of pulmonary tissue thereby rendered incapable of respiration would be comparatively small; the general distress resulting therefrom might be naturally expected to be comparatively trifling, and the physical signs would almost necessarily be less salient and characteristic. Now, I would ask, do not such diversified conditions really exist? Is it not true that pneumo-thorax may and does occur when very little disease exists in the lung, as well as when the organ is consolidated, riddled with cavities, or adherent nearly in every part; that the symptoms vary much in severity and duration, from distressing and alarming collapse, terminating in death after a very few hours, to the very chronic and scarcely observable affection, the approach of which has been unnoticed, and the duration of which extends over weeks and months, and even years? Is it not perfectly intelligible, upon the theoretical grounds that I have stated, that the accident which is the cause of speedy death to one should pass almost without notice in another individual*?

* Since this was written and read, I have perused the clinical lecture of Dr. Barker on a case in St. Thomas's Hospital, curiously confirmatory of the observations made above.

I have reason to believe that pneumo-thorax exists in the latter stages of phthisis much more frequently than has been hitherto supposed, and that it is not recognized, from the simple fact of its not being accompanied with any peculiar symptoms.

If, again, a person distressed by the accumulation of the fluid of a simple empyema have a portion of that fluid removed through a natural opening into one or more bronchial tubes,—if, in fact, the operation of paracentesis be performed internally, and the air, which sometimes passes into the pleura in consequence of more fluid having been evacuated by coughing, and more space left in the serous cavity than can be closed by the defective resiliency of the ribs, or the imperfect expansibility of the lung, have free egress as well as ingress through a large opening,—then after the immediate effects of the operation have ceased, and the fear of suffocation arising from the ejection of a large quantity of fluid has passed away, the patient will, in all probability, be relieved, and in reality very frequently is relieved, by the accident.

In confirmation of, or rather in addition to what has been here stated, it has been suggested to me by my friend and colleague, Dr. Rees, that, as when a part of an organ, or if there be two, when one organ is rendered incapable of action by accident or disease, another part of the same organ, or its fellow, assumes a supplementary action, and thus in some measure, compensates for the deficiency thereby induced, as is frequently seen in pneumonia, and particularly in disease of one kidney; so the more extensive has been the previous disease of the affected lung in pneumo-thorax, the larger has been the supply of blood, and the greater consequently the functional activity of the opposite lung, and therefore that not only is less blood sent to it in addition to that which it had before received, but that it is already in a condition better fitted to receive it.

I believe, indeed, that it will be generally found that *ceteris paribus* the less diseased the lung, and the smaller, within certain limits, the opening into the pleura, the greater will be the distress on the occurrence of pneumo-thorax, and conversely, the more diseased the lung, the greater the extent of pleuritic adhesions, and the larger the opening, the less will be the anxiety and collapse after that accident.

I am not prepared to assert that this will be found universally true; but I can certainly state that in many cases where the symptoms have been very severe and well marked, and the disease has been rapidly fatal, there has been found comparatively little disease of the lung itself, and the opening into the pleura has been small or not discovered; and conversely, that where the cessation of the complaint has been un-

noticed, or indicated by slight symptoms; and the disease has continued for many months, extensive disorganization of the pulmonary tissue, which had pretty evidently existed previously to the accident, has been discovered after death. Dr. Townsend's case, and two which will be subsequently related, may be advanced in confirmation of the one position, and Dr. Stokes', Dr. Houghton's, Dr. Barlow's, and some cases appended to this paper, may be quoted in support of the other.

This leads me to say a very few words on the appearances presented by the opening into the pleura, the especial morbid anatomy of the affection. If no fluid escape from the lung at the time of the rupture, pleuritis does not necessarily follow, or the patient may die previously to its occurrence. When, as most commonly happens, pneumo-thorax arises from the bursting of a phthisical cavity, it is usually followed by pleuritis and effusion. The aperture is then generally situated in the upper lobe, or, as stated by Dr. Houghton, at the lower edge of the upper lobe, immediately below the thick pleuritic cap, or coating, which so frequently covers the apex of the lung in phthisis. The opening, as I have previously noticed, is sometimes to small, or so covered with albuminous matter, as not to be seen after even minute examination, and can only be discovered by the use of the blow-pipe, which rarely, and as far as I have hitherto observed, never, fails to disclose it. When the accident occurs, as in two examples to be afterwards mentioned, in cases of diffused phthisis without cavities, the aperture may exist in any part of the lung, as every part is almost similarly affected. I have seen one case, in which, though cavities existed at the apex, the aperture in the pleura was found in the inferior acute edge of the lung. After the disease has lasted for some time the opening sometimes increases in size, and its edges become rounded and obtuse. In Dr. Houghton's very interesting case in the Dublin Journal, there were several openings, one or more of which appeared to him to be undergoing a process of contraction, which might subsequently have led to their obliteration. When pneumo-thorax exists as a complication to empyema, the opening into the pleura is occasionally large, and appears as if lacerated; more frequently, however, there are many minute cribriform openings, by which the sero-purulent fluid oozes through the membrane into several bronchial tubes. When pneumo-thorax arises from gangrene of the lung and pleura, the openings are irregular and undefined, but generally large, loose, and flocculent.

[To be continued.]

ON THE
EFFECT OF THE COD'S LIVER
OIL UPON STRUMOUS AND
OTHER DISEASES.

By W. O. CHALK, Esq.

(For the London Medical Gazette.)

[Concluded from p. 419.]

CASE XIX.—George Whitwell, æt. 11, admitted May 22d. Strumous hypertrophy, with abscess of the left elbow-joint; ulcer on the outer ankle; he is suffering under great derangement of the digestive organs. Having undergone the usual treatment with excellent effect up to July 19th, Ol. J. A. was prescribed: it produced nausea for the first three days; after this he felt no inconvenience, with the exception of a slight action on the bowels. He says that he began to feel stronger a few days after its exhibition; he has gained flesh, and his general appearance is that of good health. Discharged Oct. 25th, greatly improved in every respect.

CASE 20.—George Clarke, æt. 14, admitted May 23d: phthisis. Extensive deposition of tubercular matter in the upper portions of both lungs, especially on the right side; strumous enlargement of the cervical glands, with ulcers; caries of several of the phalanges of the fingers and toes; ulcers on the legs and arms; he is in a dreadful state of emaciation and disease. This patient began taking the oil July 12th; at first it produced violent nausea and acted shalply on the bowels, even when the dose was diminished from ʒss. to ʒiij. Some time elapsed before he conquered his repugnance to it. He continued to improve very much up to Sept. 9th: during this period the wounds had become more healthy; his appetite improved; he felt stronger, and had gained flesh. After this the oil seemed to lose its effect. He was discharged Oct. 19th, rather better than when he came into the house; the pulmonic symptoms had certainly undergone no increase.

CASE XXI.—Thomas Connor, æt. 9, admitted May 14th: strumous hypertrophy of the right foot, with caries of the bones of the arch; there is a large foul ulcer on its outer side, discharging a highly fetid and unhealthy pus; the left hand is hypertrophous, with caries of the last phalanges of the third and little fingers; he is in a state of extreme debility and emaciation.

July 12th.—Very slight relief having been obtained by other treatment, the oil was prescribed; the usual inconvenience followed its first exhibition. An almost immediate and beneficial effect was exerted on the local and

general symptoms. He left the Infirmary Oct. 27, very much benefited.

CASE XXII.—Wm. Murdock, æt. 9, admitted May 12: a very severe case of porrigo favosa, of five years' standing, with *leptitudo* of both eyes. As he had made very little progress up to July 20th, the oil was prescribed in the usual manner, which he continued taking up to the present date, Oct. 25th. He is now quite well. It is worthy of remark that this patient has been received into the Infirmary for the three preceding seasons, having never obtained more than partial relief.

CASE XXIII.—Robert Brideson, (out-patient), admitted May 16th: caries of the inferior maxilla on the right side; the child is in a very debilitated state; several small portions of bone were removed during the time he was here last year. He had been gradually recovering up to July 29th (nearly the whole of the remaining portion of the jaw-bone having been removed during that time) when there was an evident tendency to caries of the opposite side, evinced by enlargement of the bone, heat and swelling of the soft parts, and impending suppuration. Ol. J. A. ʒiij. was ordered to be given three times a day.

Oct. 23d.—He has continued taking it up to the present time. During the last fortnight the dose has been diminished to ʒij., as it acted too freely on the bowels. The disposition to caries on the left side has been fairly arrested; there is a sinus beneath the chin, and a small portion of bone at the symphysis, yet to come away, being the remains of the former disease; his general health is excellent, and he has gained flesh.

CASE XXIV.—Henry Hough (out-patient), æt. 5, admitted June 2d, suffering under strumous enlargement of the glands on both sides of the neck.

Sept. 29th.—Ol. J. A. was prescribed in the usual manner, and persevered in up to the day of his discharge.

Oct. 21st.—His general health has undergone rapid improvement since he has been taking it, and the glands have recovered their natural size.

CASE XXV.—Eliza Brand, æt. 23, admitted May 8th: a very enlarged state of the cervical glands on both sides, with ulcers; she complains of great pain; the head is bent forwards; any attempt to raise it adds materially to her sufferings; her general health is greatly impaired from derangement of the digestive organs; moderate pressure in the epigastrium causes acute pain; she has been ill seven years. The general treatment consisted in the application of leeches and blisters to the epigastrium, alterative aperients, enemata, tonics of sarsaparilla, colomba bark, wine, &c. The local remedies were lotio. acid. nit.

carrot, conium, and bread poultices, &c. Under this plan the symptoms (which were unusually obstinate) yielded, and though very weak, she was much relieved generally and locally.

July 29th.—The oil was prescribed (ʒiij. three times a day), which she persevered in taking up to Sept. 25th, when it was discontinued, as she complained of headache and constriction of the chest, which she insisted were produced by the Ol. J. A. Previous to this time she had recovered her health and strength, had gained flesh considerably, the glandular affection was greatly relieved, and the ulcers for the most part healed.

Oct. 16.—Recommended taking it, and has continued doing so up to the present date, Oct. 23rd, without producing any unpleasant symptoms. During the interval of cessation she suffered from a severe attack of diarrhoea, which somewhat reduced her. She is, however, surprisingly recovered, considering the duration and severity of the symptoms. She states that the oil produced nausea for the first seven or eight days, and that it was full a fortnight before any beneficial effect was perceptible.

CASE XXVI.—Anne Shepherd, æt. 22, admitted May 17: a large and deep-seated chronic abscess beneath the gluteal muscle extending about two-thirds of the way down the thigh beneath the fascia; the leg and foot are much swollen; she is unable to move the limb, and suffers severe pain at times; her general health is delicate; the disease commenced about two years since. After persevering in the usual treatment up to August 10, with considerable benefit, the symptoms suddenly altered for the worse; she complained of great debility, and there was a disposition in the abscess to point, indicated by increased pain, heat, redness, and swelling of the parts; the slightest movement in the limb caused great suffering. Ol. J. A. ʒss. was ordered to be taken three times a day; it produced so much nausea that she could only take one dose during the four and twenty hours for the first few days, afterwards it was continued as prescribed until Oct. 11th. During this interval her health had improved; she had gained flesh; the pain was relieved; the abscess diminished from absorption, and the swelling of the leg and foot much subsided; she now experienced a sensation of constriction in the chest, accompanied by pain and weight at the epigastrium after meals; the tongue was furred; the oil was omitted, and the bowels relieved by a mixture of sarza and colomba, with pil. hyd. chlor. co. grs. v. om. nocte. During the last five weeks an ointment of the iodide of mercury has been occasionally applied to the thigh, and gentle support

given to the walls of the abscess by the many-tailed bandage.

Oct. 21st.—She can now walk with ease by the aid of crutches; is quite free from pain, and is in every respect greatly relieved.

CASE XXVII.—Ann Hemming, æt. 14, admitted Aug. 5, 1843: strumous synovitis of the right knee-joint, with a large deposition of tubercular matter on the inner side of the thigh just above the articulation, forming a tumor of great size; hypertrophy of the left elbow, with abscess; it is much enlarged, she cannot flex the arm, and suffers severe pain in it and the knee at times; she walks with great difficulty by the aid of a stick; her general health is much impaired, from a disordered state of the digestive organs; she has been ill twelve months. As she improved but slowly under the usual treatment, the oil was prescribed Sept. 11, and continued up to the present date, Oct. 21st. The tumor has undergone a rapid diminution during the time, being scarcely one-third of its former size; the synovitis is relieved; she walks without a stick free from pain; the elbow is much better; her general health has undergone great improvement, and she has gained flesh.

Nov. 27.—Since taking the notes of this case, I have had an opportunity of seeing the patient. A further amendment has taken place under the exhibition of Ol. J. A. The knee is nearly of its natural size.

CASE XXVIII.—F. S., æt. 10, outpatient, admitted May 15. Was here during last season, and obtained considerable relief; she has been suffering from disease of the right hip and knee joints for eighteen months past; there are two small sinuses on the outer side of the former, with slight discharge; and several ulcers around the latter, being the result of abscess; it is much contracted, and any attempt at flexion or extension causes pain. She has been subject to epileptic fits for several years past; these, however, have been far less frequent and severe than formerly; she has had but two attacks during the last twelve months; her health is delicate: as there was a tendency to a recurrence of the fits, the wounds not so well, and the digestive organs deranged,

July 29.—Ol. J. A. ʒiij. ter. die. was prescribed: at first it produced the usual effect. She continued taking it up to Sept. 29th, with the most marked improvement in the general and local symptoms. After this it was suspended for a fortnight, as it acted too freely on the bowels and produced nausea.

Oct. 21st.—She has regained a considerable degree of motion of both articulations, and has no pain in the knee-joint on partial flexion or extension; the ulcers are

for the most part healed; her health is now excellent, and she has gained flesh surprisingly; her countenance, formerly pale, has now a ruddy aspect.

CASE XXIX.—Eliz. Barret, æt. 12, admitted July 11th: a very contracted state of the right knee-joint, consequent on synovitis; the calf of the leg is closely flexed on the thigh; there is a small ulcer over the head of the tibia; her health appears to be tolerably good. The disease has existed twelve months. Local means only were used, and with good effect up to Aug. 16th. At this time the knee became painful, accompanied by swelling, heat, and redness. Ol. J. A. ter die was ordered, which produced nausea, &c. for the first two or three days. Two doses only were administered in the twenty-four hours, which gave the most decided relief.

Oct. 23d.—All pain, heat, and redness, have subsided; the articulation can be freely moved, causing no suffering; the angle of the contraction is much lessened; the ulcer is smaller, but still unhealed; she has gained flesh and strength.

CASE XXX.—Phœbe Stodhart, æt. 10, admitted Sept. 11: incipient phthisis; the right lung is the seat of tubercular deposit, and small cavity at its summit. She has no cough; the digestive organs are much deranged; there is a superficial malignant ulcer on the right cheek, about the size of a crown piece, exceedingly irritable and painful, with an ichorous discharge, forming a tough scab; it is much allied to lupus in its character. Ol. J. A. was ordered to be taken three times a day; the scab was removed daily with a pair of small forceps, and afterwards dressed with ung. hyd. iod.: occasionally hyd. iod. was applied in powder, and sometimes a saturated solution of iodine and hydriodate of potass by the aid of a camel's hair pencil. This plan of treatment was pursued until she left the Infirmary, Oct. 21th. Her general health was greatly improved, and she had gained flesh: there was no increase in the pulmonary affection; the ulcer had lost its malignant character, and was diminished in size.

Dec. 3d.—Since writing the foregoing remarks, I have seen this patient; the same treatment has been pursued, with further success; the ulcer is fast healing, being about the size of a shilling.

CASE XXXI.—Susan Oram, æt. 10, admitted May 11th: strumous enlargement of the cervical glands, with ulcers; the digestive organs are much deranged: she has been ill three years. Under the application of leeches to the epigastrium, aperients, alteratives, tonics, &c. together with a suitable local treatment, she improved considerably; but as she still suffered from occasional attacks of headache and obstinate

constipation, the tongue being furred, countenance sallow, and the ulcers unhealed, July 20th, I prescribed Ol. J. A. ʒss. ter die, which gave rise to the usual inconvenience for the first few days.

Oct. 23d.—She has continued taking it with regularity up to the present date, and is quite well. The ulcers are healed; the headaches have ceased; the constipation is relieved; the tongue clean; her countenance clear and healthy, affording a great contrast to its former sallow hue, and she has gained flesh.

CASE XXXII.—E. H., æt. 4: is suffering severely from porrigo, affecting the scalp and face (*P. larvalis*); her general health is greatly impaired, and she is much emaciated.

July 20th.—Three drachms of the oil were ordered to be given three times daily. She has continued taking it up to the present day, October 21st, and is quite well.

CASE XXXIII.—Sophia Day, æt. 5: strumous ophthalmia of a very severe character. The corneæ are ulcerated; there is onyx of the left eye; the deposition extends nearly half way up the cornea; the conjunctival vessels are gorged; eyelids swollen; great intolerance of light, and profuse epiphora. These symptoms are accompanied by low irritative fever. It was quite clear that unless prompt relief were afforded, loss of sight of the left eye must speedily ensue. A grain of calomel was ordered to be given every two hours; a leech to be applied to the left lower eyelid, and the bleeding to be promoted for some hours; careful exclusion of light, and perfect rest. On visiting the child in the evening, I found that the person who had charge of her, had, of her own accord, administered three tea-spoonfuls of Ol. J. A. which, together with the calomel, had acted freely on the bowels, and relieved the eyes very much. I directed the dose of the oil to be repeated early in the morning, and other treatment to be discontinued. On going the following day, I found the patient sitting up; the intolerance of light and flow of tears had greatly abated; the conjunctival vessels were less gorged, and the swelling of the lids had in a great measure subsided. The oil had been given as directed, and by 11 o'clock A.M. (the hour of my visit) had again produced several motions: from this time (July 22d) it was administered with regularity three times daily. In less than four days from its exhibition, the conjunctivæ had regained their usual whiteness; ulcers on the cornea had taken on a healing action; the deposition in the left eye was completely absorbed, and the febrile symptoms entirely allayed. She continued taking the oil with the most marked benefit until September 15th, at which time it produced nausea and a very relaxed state of the bowels.

It was resumed October 7th, and continued up to the present date, October 21st. The eyelids alone remain slightly affected; she has gained flesh and strength; her appetite is excellent; tongue clean, and pulse natural.

CASE XXXIV.—Emily Drummond, æt. 17, admitted May 15th: enlarged cervical glands and strumous ulcers: began taking the oil in doses of ʒij. twice a day: it produced languor, heaviness, headache, and sickness. The quantity was diminished to ʒj., and continued at intervals for eight weeks; but at the end of that time she ceased taking it, as these symptoms became urgent.

CASE XXXV.—Sarah Smith, æt. 35, admitted August 31st: pompholix of five months' standing. The Ol. J. A. was prescribed in ʒij. doses. Violent vomiting and purging, with prostration of strength, ensued, and lasted for several hours.

CASE XXXVI.—Palisia Lloyd, æt. 9, admitted July 15th: strumous abscess in the left thigh; great debility and emaciation. She had suffered from diarrhoea a fortnight previous to taking the oil. It recurred with violence, accompanied by severe vomiting, after taking one dose.

CASE XXXVII.—James Sheppard, æt. 41, admitted May 11th: rheumatic affection of the right hip-joint, with effusion within the capsular ligament. Dyspeptic symptoms followed the exhibition of the Ol. J. A. viz. weight in epigastrio, sickness, headache, constriction of the chest, and constipation. No beneficial effect was produced on the local disease.

CASE XXXVIII.—James Deady, æt. 13, admitted: tabes mesenterica, enlarged cervical glands, diarrhoea: he is much debilitated and emaciated. The oil was prescribed some time after the diarrhoea had ceased. The first dose produced a recurrence of it, violent vomitings, and great prostration of strength.

CASE XXXIX.—Henry Ashley, æt. 35: rheumatic ophthalmia, granular eyelids, great intolerance of light. The oil produced dyspeptic symptoms, which were followed by an increase of the ophthalmia.

CASE XL.—H. Enptage, æt. 53 (mariner), of Margate, out-patient: enlarged liver, incipient ascites, strumous enlargement of the cervical, axillary, and inguinal glands, deposition of tubercular matter at the summit of the right lung. The oil was exhibited some time after he had recovered from a severe attack of English cholera. A table-spoonful of the oil reproduced it, and was followed by great prostration of strength.

ON A

RELATION EXISTING BETWEEN THE SITUATION OF HAIR UPON THE HUMAN BODY, AND CERTAIN SUBJACENT TISSUES.

By THOMAS HAWORTH, M.D.

(For the London Medical Gazette.)

“In the study of anatomy, every man proceeds on the axiom, that nothing in the body of an animal was made in vain; and when he meets with a part of which the use is not obvious, he feels himself dissatisfied till he discovers some at least of the purposes to which it is subservient.” It is unnecessary to say that the situation of the various patches of hair on the human body cannot be referred to mere accident, there is some special reason why hair should abound on one part of the body, and be absent or scanty on another. I think it may be shown, that generally speaking hair is the most plentiful in those situations where bone, tendon, fascia, or cartilage, lie near the surface.

The head affords the most striking example. The cranium has very little fleshy covering, and is accordingly supplied with a plentiful growth of hair. The forehead, indeed, is bare, for if it were otherwise vision would be interfered with. This exception, however, tends in a singular manner to confirm our position that some relation exists between the site of hair and the subjacent tissues, for very generally the margin of the hair at the upper part of the forehead imitates pretty exactly a line drawn along the junction of the belly of the frontal muscle, with its tendon; the upper part of each division of the frontal muscle is rounded, and its tendon, of course, bounds the rounded portion of each, dipping between them towards their junction at the middle of the forehead; the hair very frequently does precisely the same, forming a projecting tongue at the summit of the forehead. This similarity is too remarkable to be the result of accident.

At the back of the neck we may observe the growth of the hair descend in the form of three processes; two of them upon the insertions of the splenic muscles, and the other upon the cervical vertebrae; in the last situation, we

have in quadrupeds the coincidence of the ligamentum nuchæ, and the mane.

The whole course of the jaw-bone is marked out by the whiskers and beard, a prolongation proceeding to the malar bone, which stands out exposed. The point of the chin having no muscular covering, exhibits an earlier and more plentiful beard than the neighbouring part, the skin on each side covering the depressor labii inferioris being comparatively bare. This tuft being the first promise of manhood on the chin, is very much cherished by the rising generation. The cartilage of the larynx is very generally protected by an extension of the beard.

After the cranium, the sternum presents the largest surface of bone which is but slightly covered with fleshy parts, and, in obedience to the rule with which we started, it receives a covering of hair. It is to be observed that the tendinous origin of the pectoralis major becomes broader at the upper part of the sternum, and that there is often a corresponding increase of hairy surface at the same place.

We now come to the abdomen, the parietes of which, at the lower part, are almost entirely composed of tendinous substance. Here, also, we find hair extending upwards along the *linca alba*, forming a patch of hair of much the same shape and size as the tendinous expansion of the abdominal muscles.

The exposed aspect of the foot and hand have also hairs growing on them.

When patches of hair occur in unusual situations, the same coincidence is frequently observed. Thus I have seen the acromion processes covered with hairy epaulettes, and the whole length of base of the scapula fringed with a narrow line of hair. There is a portion of the posterior part of the ribs, near the lower angle of the scapula, which in one part is covered only by the tendinous insertions of the sacro-lumbalis muscle, and in another has only a thin additional covering from a part of the *latissimus dorsi*; on this spot I have seen a patch of hair. The *os sacrum* is sometimes similarly covered.

The above coincidences of the occurrence of hair in places where bone, cartilage, fascia, or tendon, lie near the surface, are, I think, too numerous to be accidental. If we take a connected view of the three great cavities of the

body, the cranium, thorax, and abdomen, we shall be forcibly struck with this coincidence. The parietes of all receive a covering of hair in those places where there is little muscular substance; that is, where bone, cartilage, fascia, or tendon, lie near the surface: we have hair on the head, on the sternum, and on the abdominal fascia. There are, no doubt, exceptions to the rule, but they are neither numerous nor important, and are not sufficient to neutralize the instances in accordance with it.

It is easy to conjecture the final cause of this coincidence. The above-mentioned tissues have this in common, that *they are all scantily supplied with blood*. Without an extra protection, therefore, the temperature of the integument covering them, and of the parts underneath, would rapidly approach that of the external air. The aching cold felt when the forehead, chin, and other parts similarly circumstanced, are exposed to a low temperature, must be familiar to every one. The exposure of a bald or shaven head to intense cold, no doubt injuriously affects the functions of the brain, unless it is applied as a remedy in cases of undue vascular excitement.

Here it will not be out of place to make some observations on the common practice of applying cold to the head. It will be readily understood that, as there is nothing intervening between the integument of the head and the brain, except a thin muscle, bone, and thin membranes, which can generate little heat, but which, being dense, can conduct it rapidly, the application of cold to the forehead and shaven head must cool the brain almost as quickly as if it were applied directly upon it. This fact should teach us to be circumspect in using this remedy. It would seem to be the prevailing opinion that the brain is in a blaze whenever there is headache or any affection of the nervous system, and that we must proceed to extinguish it with the activity of a fire brigade. The peculiar nature of many of the nervous symptoms may perhaps account for this practice. When a patient has presented to his imagination objects of the most dazzling colour, and declares he is surrounded with flames of fire, we are nearly inclined to believe that the source of these vivid sensations, the

brain, must be a fiery furnace indeed ; forgetting that the aurora borealis is most and best seen in the cold atmosphere of arctic regions. In short, the sensations above mentioned may arise from an exhausted and collapsed brain, when the constant application of freezing cold would most probably produce injurious effects, and where it would be judicious to maintain a moderate warmth of head. It is probable that, in hypochondriacal cases attended by a sense of weight, pressure, constriction and pain, warm and stimulating applications to the head might give relief. The recommendation to keep the head cool and the feet warm is not applicable to all cases ; there are many where both should be kept warm. Nature had some motive in providing the head with a covering of hair. When it is judged expedient to apply cold lotions to the head, they ought to be such as are capable of being entirely evaporated. If vinegar be used, it should be distilled or pyroligneous acid diluted with water. By the use of common vinegar, the head is liable to become varnished with a coating of mucilage, causing an injurious interruption to the functions of the skin. Lotions composed of the solutions of salts are objectionable when applied to the head, as they leave a crystalline incrustation. In short, whatever lotion is employed should have no residuum after evaporation—no *caput mortuum* attached to the living head. I would refer to Dr. Graves' "Clinical Medicine" for some useful observations on cold and warm applications to the head.
